The first nationwide system of electronic navigational aids was composed of several hundred low frequency "four-course ranges." At each range station the international Morse code letter for *N* (▬ •) is transmitted in two opposite sectors called "quadrants." In the other two "quadrants" the letter *A* (• ▬) is transmitted. These signals are so related that along the boundaries between sectors, where the two signals are of equal strength, the dots and dashes interlock to form a continuous monotone. It is possible to control the direction of these monotones or "beams" so that they indicate desirable directions of travel. Along these "beams" a series of **airways** are established, somewhat resembling highways. The *magnetic* directions of these beams are indicated on the chart, as shown in figure 2802. To use these ranges the navigator has only to follow one leg to the station and another leg out until he picks up the next beam.

These ranges are being supplemented by a series of very high frequency **vortac** stations. Each vortac station provides two methods of establishing direction, and means for determining distance. The two direction systems are **tacan** (**tac**tical **air navigation**) for military aircraft, and **omnirange** (**VOR**) for commercial and private aircraft. The suitably equipped aircraft is thus provided an infinite number of "radials" (in practice 360 at 1° intervals around each station) by means of which an aviator can receive guidance along *any* radial line from the station. With direction and distance available at all times, a continuous fix is provided, whether or not the

aircraft is following a radial. If the aviator selects the radial he wishes to follow, a dial indicates when he is off the radial, and which direction he should turn to get back on it. A "TO-FROM" indicator tells the aviator whether the selected radial is to be measured toward or away from the station. If the aircraft is equipped with a **course computer,** he can fly toward or away from an offset **way point** with the same indications as though it were the range station. Thus, multilane airways are available.

Longer range aids used by aircraft, particularly over ocean areas, include loran (art. 1302), Decca (art. 1309), and consol (art. 1312). A number of other systems have been suggested, and the future will undoubtedly see an increase in the use of electronics in air navigation, particularly in dead reckoning and celestial systems.

Airborne radar is a valuable navigational aid. With practice one can learn to identify the echoes from different features of the terrain, and often to locate his position by piloting methods when the surface is obscured by an undercast.

Various beacons are designed primarily for use by aviators. A **racon** is a **ra**dar bea**con** which returns a coded signal when triggered by a signal from the aircraft's radar, thus providing identification as well as bearing and range. **Fan markers** transmit vertical fan- or bone-shaped patterns at selected points along an airway to indicate passage of those points. Nondirectional markers are placed at other points. Above each station of a four-course range an inverted **cone of silence** occurs, where little or no signal from the ranges is received. At some of these stations **Z markers** are installed to transmit distinctive signals upward to indicate location of the stations.

2806. Celestial navigation.—In the air, celestial navigation is used in polar regions and on long over-water flights. Observations are invariably made with some form of artificial-horizon sextant (art. 1513), usually one having a bubble or pendulum reference. In air navigation, positions are needed more often than on land or sea. An entire flight across the Atlantic may be made between evening twilight and dawn. A common practice over the oceans is to obtain fixes at intervals of one hour. Another reason for using an artificial-horizon sextant is that the natural horizon is often obscured by clouds or haze, while celestial bodies are clearly visible. If a periscopic sextant (fig. 1513a) is not available, observations are usually made through an astrodome.

Because of the speed of aircraft, time zones may be crossed at frequent intervals. It is customary to keep navigational timepieces set to GMT. For celestial navigation, a high-grade watch is carried. It may have a 24-hour dial, and in most instances it has a sweep second hand.

Rapid sight reduction is important at aircraft speeds. In ten minutes a modern plane may travel 100 miles. The method most commonly used is H.O. Pub. No. 249 (art. 2113), with the *Air Almanac*. By precomputation, a navigator can obtain a fix within two or three minutes after the observations. Observation at a selected time is not a problem, because the sight continues over a period, usually two minutes, during which an averaging device is in operation. This eliminates large acceleration errors that might arise from motions of the aircraft. Thus, ten minutes may be required for observation of three stars at four-minute intervals between the mid times of observation. Celestial observations in the air are inherently less accurate than good observations with a marine sextant aboard ship. In the air an error of five to ten miles is considered normal for favorable conditions.

As speeds increase, the need for faster observation and reduction becomes more urgent. This has lead to development of automatic celestial navigation (art. 2124).

2807. Pressure pattern navigation.—On a long over-water flight, the great circle is a good approximation of the shortest distance between point of departure and destination. However, it may not be the least-time route, because of unfavorable winds. At more than one or two thousand feet above the surface of the earth, winds tend to

blow along the isobars (except near the equator). If the pattern of isobars (the "pressure pattern") at flight altitude is known, an experienced air navigator can often select a route that may add miles to the flight but increase ground speed to such an extent that time is reduced. This is one form of **pressure pattern navigation.**

A pressure pattern flight is customarily made at a constant *pressure* altitude (for instance the 500-millibar level at a standard altitude of 18,281 feet). By means of barometric and absolute altimeters, the navigator is able to determine any increase or decrease in height of the constant pressure surface over a time interval. With this information, he is able to compute the cross component of the wind, or the lateral drift. This is of assistance in dead reckoning, and it serves as a check on predicted pressure and wind. It is the basis for alterations that may be needed in the original plan.

2808. Flight planning.—Before take-off, a careful study is made of weather conditions expected to be encountered en route and at the terminal. If a choice of route and altitude is available, the most favorable are selected. Wind triangles for various parts of the flight are solved, and heading and ground speed determined. From this, the flight *time* and the amount of fuel needed for the flight can be computed. A suitable **alternate aerodrome** is selected for use if weather makes landing at the scheduled destination hazardous. Fuel deemed sufficient for the flight to the destination and then to the alternate, plus the amount needed for warm-up and take-off, and an adequate reserve, is taken aboard.

During the flight a close check is kept upon the actual rate of fuel consumption, and if this exceeds the predicted rate to such an extent that there is danger of exhausting the fuel supply before reaching the destination, the aircraft returns or is diverted to another aerodrome.

An adequate flight plan, properly used, is vital to safe flight over long distances. The plan is filed at the aerodrome of departure or other designated place, which notifies the destination of the **estimated time of arrival** (**ETA**). During the flight, periodic reports by radio provide information on progress and deviations from the plan. These serve as the basis for search and rescue operations, should they become necessary.

2809. Space navigation.—Navigation of a spacecraft through the atmosphere of the earth and beyond left the realm of science fiction and became a reality with the first successful launching of an artificial earth satellite in 1957. The same basic principles that govern terrestrial navigation are involved in space navigation, but with some differences of technique and emphasis.

Space navigation is four-dimensional, in contrast to the essentially two-dimensional navigation on or near the surface of the earth. In addition to the obvious third dimension of space, time has increased significance. Progress toward a final point is, by itself, inadequate. One must arrive at the point at the right instant to effect satisfactory rendezvous with another moving object. Neither direction of motion nor speed is directly measurable to satisfactory accuracy for navigation, and both motion and speed are likely to be varying continually. With the tremendous speeds involved and serious power limitations, only minor corrections to either speed or direction are likely to be available. There is little probability of recovering from a serious mistake.

Because of the fantastic distances and the propulsion systems now considered feasible, flight times to the nearest stars will be measured in life spans. Consequently, meaningful space navigation in this century is likely to be limited to the solar system. The techniques expected to be used during this period differ somewhat in each of four phases of space flight: (1) escape, (2) in the near vicinity of a celestial body, (3) midcourse, and (4) terminal.

During escape, whether from the surface of the earth or an orbit around it, a carefully precalculated trajectory is followed. Tracking is performed from the earth. Acceler-

ometers control the cutoff at the desired speed. All space missions are so carefully planned in advance that the need for later corrections is dependent directly upon the accuracy with which the escape phase navigation is performed.

In the vicinity of a celestial body, as in the escape phase, position is determined with respect to the body involved. The coordinate system used is (1) distance from the body, and (2) latitude and longitude on the sphere thus identified. This might be determined from the celestial body, as is commonly done with artificial earth satellites and space probes from the earth, or it might be determined from aboard the spacecraft. Distance from the celestial body might be determined by radar or by measurement of the apparent diameter of the body. Position on the sphere can be established by observation of the position of the body among the background of stars, thus establishing celestial lines of position.

During the midcourse phase of a flight to another planet, navigation is primarily a matter of determining position and comparing it with the scheduled position at the time of fix. Thus, dead reckoning and position fixing serve the same functions as on earth. Position determined relative to other bodies of the solar system is a form of piloting. Celestial navigation involves use of the background of stars. Position is identified as distance from the sun and some form of "latitude" and "longitude" on the sphere thus identified. Distance from the sun can be determined directly by measurement of its apparent diameter. Optical measurement of the angle between lines of sight to a planet and star establishes position on a cone having its apex at the planet. Two such cones each with its apex at the same planet intersect in two lines, and a third cone will remove the ambiguity. Three-dimensional position can also be determined by means of cones referred to three bodies of the solar system or by means of celestial lines of position on two such bodies, noting their positions relative to the background of stars. A discrepancy in scheduled position might be corrected by (1) returning to the original schedule at a specific time, (2) establishing a new path to intercept the destination planet at the original time and place, or (3) determining a new optimum path to intercept the planet.

During the terminal phase, thrust is applied to place the spacecraft in an orbit around the destination planet or guide the craft to a soft landing. Position is determined with respect to the body being approached. It is important that the dead reckoning be advanced far enough ahead to allow timely alteration of path, if needed, to place the spacecraft in an appropriate position for carrying out terminal phase maneuvers.

When continuous thrust of relatively small power becomes available, a procedure which will greatly simplify the navigation will be to proceed first to the line connecting the sun and destination planet and then to apply continuous thrust to stay on this line, reaching the destination by homing techniques.

Use of some kind of physical phenomena has been suggested for either establishing lines or surfaces of position, or measuring either speed or direction of motion. This approach has not been promising.

The present state of the art seems adequate to develop a fully automatic system for navigation during any space mission possible. However, a considerable amount of engineering will be needed before a reliable system is available.

CHAPTER XXIX

NAVIGATIONAL ERRORS

2901. Introduction.—As commonly practiced, navigation is not an exact science. A number of approximations which would be unacceptable in careful scientific work are used by the navigator, because greater accuracy may not be consistent with the requirements or time available, or because there is no alternative.

Thus, when the navigator uses his latitude graduations as a mile scale, or computes a great-circle course and distance, he neglects the flattening of the earth at the poles, a practice that is not acceptable to the geodetic surveyor. When the navigator plots a visual bearing, or an azimuth line for a celestial line of position, on a Mercator chart, he uses a rhumb line to represent a great circle. When he plots the celestial line of position, he substitutes a rhumb line for a small circle. When he interpolates in tables of logarithms or in loran tables, he assumes a linear (constant-rate) change between tabulated values. When he measures distance by radar, or depth by sonic depth finder, he assumes that the radio- or sound-wave has constant speed under all conditions. When he applies dip and refraction corrections to his sextant altitude, he generally assumes standard atmospheric conditions.

These are only a few of the approximations commonly applied by a navigator. There are so many that there is a natural tendency for some of them to cancel others. Thus, under favorable conditions, a position at sea, determined from celestial observation by an experienced observer, should seldom be in error by more than two miles. However, if the various small errors in a particular observation all have the same sign (all plus or all minus), the error might be several times this amount, without any mistake having been made by the navigator.

Greater accuracy could be attained, but at a price. The navigator is a practical individual. In the course of ordinary navigation, he would rather spend ten minutes determining a position having a probable error of plus or minus two miles, than to spend several hours learning where he *was* to an accuracy of a few yards. But if he can determine a recent or present position to greater accuracy, the decrease in error is attractive to him. The various navigational aids have been designed with this in mind. Greater accuracy in plotting could be achieved by increasing the scale of the chart or plotting sheet. This has been done for confined waters where a higher degree of accuracy is needed, but a large-scale plotting sheet would be a nuisance at sea. The hand-held marine sextant is not sufficiently accurate for use in determining an astronomical position in a geodetic survey. But it is much more satisfactory at sea than the surveyor's astrolabe or theodolite (arts. 4002, 4004), which require stable platforms if their potential accuracy is to be realized.

An understanding of the kinds of errors involved in navigation, and of the elementary principles of probability, should be of assistance to a navigator in interpreting his results.

2902. Definitions.—The following definitions apply to the discussions of this chapter:

Error is the difference between a specific value and the correct or standard value. As here used, it does not include mistakes, but is related to lack of perfection. Thus, an altitude determined by marine sextant is corrected for a standard amount of refraction,

but if the actual refraction at the time of observation varies from the standard, the value taken from the table is in error by the difference between standard and actual refraction. This error will be compounded with others in the observed altitude. Similarly, depth determined by echo sounder is in error, among other things, by the difference between the actual speed of sound waves in the water and the speed used for calibration of the instrument. It will also be in error if an echo is returned from a phantom bottom (art. 3504) instead of from the actual bottom. This chapter is concerned primarily with the deviation from standards. Thus, while variation of the compass is an error when referred to true directions, the difference between the assumed variation and that actually existing is an error with reference to magnetic direction. Corrections can be applied for standard values of error. It is the deviation from standard, as well as mistakes, that produce inaccurate results in navigation. Various kinds of error are discussed in the following articles.

Mistake is a blunder, such as an incorrect reading of an instrument, the taking of a wrong value from a table, or the plotting of a reciprocal bearing.

Standard is something established by custom, agreement, or authority as a basis for comparison. It is customary to use nautical miles for measuring distances between ports. By international agreement the nautical mile is defined as a certain number of meters. By authority of various countries which are parties to the agreement, this length is translated to the linear units adopted by that country. It is the fact of establishment or general acceptance that determines whether a given quantity or condition has become a standard of measure or quality. Thus, in 1960, the standard unit of length agreed upon at the Eleventh General (International) Conference on Weights and Measures to redefine the meter was 1,650,763.73 wavelengths of the orange-red radiation in vacuum of krypton 86 corresponding to the unperturbed transition between the $2p_{10}$ and $5d_5$ levels. Where accepted, this established standard of length now serves as a basis for measurement of any physical magnitude, as the length of the meridian, rather than the reverse, which was originally proposed. Multiples and submultiples of a standard are exact. In 1959, the U. S. adopted the exact relationships of one yard as equal to 0.9144 meter and one inch as equal to 2.54 centimeters. Hence, 39.37 U. S. inches are approximately equal to one meter. Because one foot equals 12 inches by definition, and the international nautical mile has been defined as 1852 meters, the international nautical mile is equal to 6,076.11549 U. S. feet (approximately). The previous U. S. foot (6,076.10333 . . . feet equals one nautical mile) has been redesignated as the U. S. survey foot. It will still be encountered frequently during the transitional period. The values and tables in this 1962 edition are based on those adopted by the United States in 1959.

Frequently, a standard is so chosen that it serves as a model which approximates a mean or average condition. However, the distinction between the standard value and the actual value at any time should not be forgotten. Thus, a standard atmosphere has been established in which the temperature, pressure, density, etc., are *precisely* specified for each altitude. Actual conditions, however, are generally different from those defined by the standard atmosphere. Similarly, the values for dip given in the almanacs are considered standard by those who use them, but actual dip may be appreciably different from that tabulated.

Accuracy is the degree of conformance with the correct value, while **precision** is the degree of refinement of a value. Thus, an altitude determined by marine sextant might be stated to the nearest 0!1, and yet be accurate only to the nearest 1′ if the horizon is indistinct. Accuracy and precision are further discussed in article O3.

2903. Systematic errors are those which follow some law by which they can be predicted. The accuracy with which a systematic error can be predicted depends

upon the accuracy with which the governing law is understood. An error which can be predicted can be eliminated, or compensation can be made for it.

The simplest form of systematic error is one of unchanging magnitude and sign. This is called a **constant error.** Examples are the index error of a marine sextant, watch error, or the error resulting from a lubber's line not being accurately aligned with the longitudinal axis of the craft. In each of these cases, all readings are in error by a constant amount *as long as the adjustment remains unchanged,* and can be removed by applying a correction of equal magnitude and opposite sign. Index error and watch error can be removed by adjustment of the instrument. Lubber's line error can be removed by aligning the lubber's line with the longitudinal axis of the craft.

Another type of systematic error results from a nonstandard rate. If a watch is gaining four seconds per day, its readings will be in error by one second after an interval of six hours, eight seconds at the end of two days, etc. This principle is used in establishing a chronometer rate (art. 1908) for determination of chronometer error between comparisons of the chronometer with time signals. It can be eliminated by adjusting the rate. If a current is running and no allowance for it is made in the dead reckoning, the DR position is in error by an amount proportional to elapsed time. The error introduced by maintaining heading by means of an inaccurate compass is proportional to distance, as is the lateral error in a position line plotted from an inaccurate bearing.

One of the causes of equation of time (art. 1912) is the fact that the ecliptic, around which annual motion occurs, is not parallel to the celestial equator, around or parallel to which apparent daily motion takes place. The same type systematic error is involved in other measurements. Consider the measurement of bearing with a tilted compass card. Bearing is measured by a system of uniform graduations (degrees) of a circle (such as a compass card) in the horizontal plane. If the card is tilted, and its graduations are projected onto the horizontal plane, the circle becomes an ellipse with the graduations unequally spaced. Along the axis of tilt and a line perpendicular to it, directions are correct. But near the axis of tilt the graduations are too close together, and near the perpendicular they are too widely spaced. The error thus introduced is similar to that which would arise if a watch face were tilted but the motion of the hands remained horizontal. If it were tilted around the "3–9" line, it would appear to run slow near the hour and half hour, and fast near the quarter and three-quarter hours. If the direction to be observed is of an object above or below the horizontal, as the azimuth of a celestial body, measurement is made to the foot of the perpendicular through the object. The sight vanes of a compass move in a plane perpendicular to the compass card. Hence, if the card is tilted, measurement is made to the foot of a perpendicular to the card, rather than to the foot of a perpendicular to the horizontal, introducing an error which increases with the angle of tilt and also with the angle of elevation (or depression) of the object. This error is greatest along the axis of tilt, and zero along the perpendicular to it. Both of these tilt errors can be corrected by leveling the compass card.

A different type of tilt error occurs when a reflection takes place from a tilted surface, such as the ionosphere (art. 1007), the error being proportional to the angle of tilt. In some respects, this error is similar to coastal refraction of a radio wave (art. 1006).

Additional examples of systematic error are uncorrected deviation of the compass (art. 709), polarization error (art. 1203), error due to a position in a pattern of hyperbolas (art. 1109), error due to incorrect location of a loran transmitter (art. 1306), uncorrected parallax (art. 1620), and uncorrected personal error (art. 1507).

2904. Random errors are chance errors, unpredictable in magnitude or sign. They are governed by the laws of probability. If the altitude of a celestial body is

Error	No. of obs.	Percent of obs.
−10′	0	0. 0
− 9′	1	0. 2
− 8′	2	0. 4
− 7′	4	0. 8
− 6′	9	1. 8
− 5′	17	3. 4
− 4′	28	5. 6
− 3′	40	8. 0
− 2′	53	10. 6
− 1′	63	12. 6
0	66	13. 2
+ 1′	63	12. 6
+ 2′	53	10. 6
+ 3′	40	8. 0
+ 4′	28	5. 6
+ 5′	17	3. 4
+ 6′	9	1. 8
+ 7′	4	0. 8
+ 8′	2	0. 4
+ 9′	1	0. 2
+10′	0	0. 0
0	500	100. 0

TABLE 2904.—Normal distribution of random errors.

observed, the reading may be (1) too great, (2) correct, or (3) too small. If a number of observations are made, and there is no systematic error, the probability of a positive error is exactly equal to the probability of a negative error. This does not mean that every second observation having an error will be too great. However, the greater the number of observations, the greater is the probability that the number of positive errors will equal the number of negative ones, and that their magnitudes will correspond.

Suppose that 500 observations are made, with the results shown in table 2904. A close approximation of the plot of these errors is shown in figure 2904a. The plot has been modified slightly to constitute the **normal curve** of random errors, which is the same as the actual curve except that the normal curve *approaches* zero as the error increases, while the actual curve *reaches* zero at (+)10′ and (−)10′. The height of the curve at any point represents the percentage of observations that can be expected to have the error indicated at that point. The probability of any similar observation having any given error is the proportion of the number of observations having this error to the total number of observations, or the percentage expressed as a decimal. Thus, the probability of an observation having an error of (−)3′ is $\frac{40}{500}=\frac{1}{12.5}=0.08$ (8%).

If the area under the curve represents 100 percent of the observations, half the area (the shaded portion of figure 2904a) represents 50 percent of the observations. The value of the error at the limits of this shaded portion is often called the "50 percent error," or **probable error,** meaning that 50 percent of the observations can be expected to have less error, and 50 percent greater error. Similarly, the limits which contain the central 95 percent of the area denote the 95 percent error. The percentage of error is found mathematically. For a normal curve, each error is squared, the sum of the squares is divided by one less than the number of observations, and the square root of the quotient is determined. This value is called the **standard deviation** (*s*) or **root mean square.** In the illustration, the standard deviation is the square root of $0\times(-)10^2+1\times(-)9^2+2\times(-)8^2+4\times(-)7^2+9\times(-)6^2$, etc., divided by 499 or $\sqrt{\frac{4474}{499}}=\sqrt{8.966}=2.99$ (about 3). The standard deviation is the 68 percent error. The probability of the occurrence of an error of or less than a specific magnitude may be determined by the following relationship (with the answers for the illustration given):

$$
\begin{aligned}
50\%\ \text{error} &= \tfrac{2}{3}\times s = 2' \text{ (approx.)}\\
68\%\ \text{error} &= 1 \times s = 3' \text{ (approx.)}\\
95\%\ \text{error} &= 2 \times s = 6' \text{ (approx.)}\\
99\%\ \text{error} &= 2\tfrac{2}{3}\times s = 8' \text{ (approx.)}\\
99.9\%\ \text{error} &= 3\tfrac{1}{3}\times s = 10' \text{ (approx.)}
\end{aligned}
$$

Many of the errors of navigation are not of the "normal" type. In H.O. Pub. No. 214 (art. 2003) values of altitude can be taken only to the nearest 0.′1. The error might

have any value from (+) 0.′05 to (−) 0.′05, and any value within these limits is as likely to occur as any other of the same precision. The same is true of a sextant that cannot be read closer than 0.′1, and of a loran receiver that cannot be read closer than 1μs. These values refer to the single errors indicated, and not to the total error that might be involved. This is a **rectangular error,** so called because of the shape of its plot, as shown in figure 2904b. The 100 percent error is half the difference between readings. The 50 percent error is half this amount, the 95 percent error is 0.95 times this amount, etc.

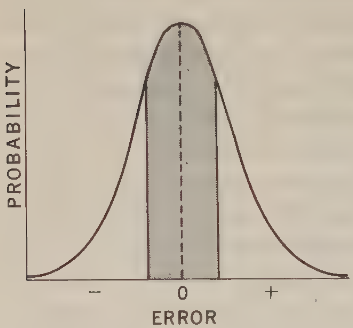

Figure 2904a—Normal curve of random error with 50 percent of area shaded. Limits of shaded area indicate probable error.

Still another type random error is encountered in navigation. If a compass is fluctuating periodically due to yaw of a ship, its motion slows as the end of a swing is approached, when the error approaches maximum value. If readings were taken continuously or at equal intervals of time, the interval being a small percentage of the total period of oscillation, the curve of errors would have a characteristic U-shape, as shown in figure 2904c. The same type error is involved in measurement of altitude of a celestial body from a wing of the bridge of a heavily rolling vessel, when the roll causes large changes in the height of eye. This type of error is called a **periodic error.** The effect is accentuated by the tendency of the observer to make readings near one of the extreme values because the instrument appears steadiest at this time. If it is impractical to make a reading at the center of the period, the error can be eliminated or reduced by averaging readings taken continuously or at short intervals, as indicated above. This is the method used in averaging type artificial-horizon sextants (art. 1513). Generally, better results can be obtained by taking maximum positive and maximum negative readings, and averaging the results.

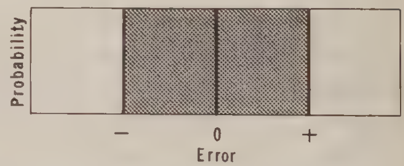

Figure 2904b.—Rectangular error, with 50 percent area shaded.

The curve of any type of random error is symmetrical about the line representing zero error. This means that in the ideal plot every point on one side of the curve is exactly matched by one on the other side, or for every positive error there is a negative error of the same magnitude. The average of all readings, considering signs, is zero. The larger the number of readings, the greater the probability of the errors fitting the ideal curve. Another way of stating this is that as the number of readings increases, the error of the average can be expected to decrease.

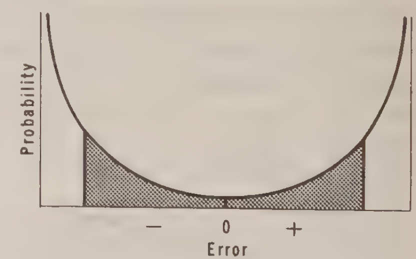

Figure 2904c.—Periodic error, with 50 percent area shaded.

2905. Combinations of errors.—Many of the results obtained in navigation are subject to more than one error. Chapter XVI lists 19 errors applicable to sextant altitudes. Some of these have several components. A number of possible errors are involved in the determination of computed altitude and azimuth. A rectangular error is possible in finding the altitude difference. Several additional errors may affect the accuracy of plotting. Thus, the line of position as finally plotted may include 30 errors or more. Corrections are applied for some of the larger ones, so that in each of these cases the applicable error is the difference

between the applied correction and the actual error. Thus, a dip correction may be applied for a height of eye of 30 feet, while the actual height at the moment of observation may be 31 feet 6 inches. Even if the height of eye is exactly 30 feet, a rectangular error may be involved in taking the dip correction from the table.

Corrections which might be random as far as an individual observation is concerned may be systematic for a series of observations. Thus, if the average or standard conditions upon which a correction is based do not exist at the time of observation the value at any given time is as likely to be greater as it is to be less than the standard amount. But if a number of observations are taken in quick succession, the error will be about the same for each.

If two or more errors are applicable to a given result, the total error is equal to the algebraic sum of all errors. Thus, if a given number is subject to errors of (+) 4, (−) 2, (−) 1, (+) 3, (+) 2, 0, and (−) 2, the total error is (+) 4. Systematic errors can be combined by adding the curves of individual errors. Thus, a magnetic compass may have a quadrantal error as shown by the top curve of figure 2905, and a semicircular error as shown by the second curve. The sum of these two errors is shown in the bottom curve. If, in addition, the compass has a constant error, the bottom curve is moved vertically upward or downward by the amount of the constant error, without undergoing a change of form. If the constant error is greater than the maximum value of the combined curves, all errors are positive or all are negative, but of varying magnitude.

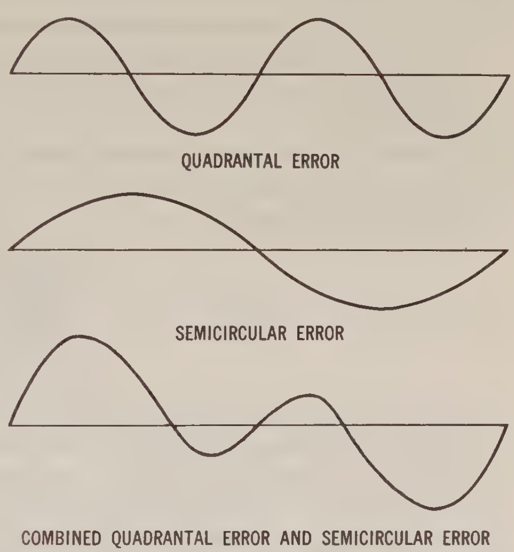

FIGURE 2905.—Combining systematic errors.

If a number of random errors are combined, the result tends to follow a normal curve regardless of the shape of the individual errors, and the greater the number, the more nearly the result can be expected to approach the normal curve (fig. 2904a). If a given result is subject to errors of plus or minus 3, 2, 1, 2, 4, 2, 1, 8, 1, and 2, the total error *could* be as much as 26 if all errors had the same sign. However, if these are truly random, the probability of them all having the same sign is only one in 1024. This is so because the chance of any one being positive (or negative) is $\frac{1}{2}$. That is, of a large number of results, approximately half will have any one particular correction positive (or negative). By the same reasoning, approximately half of the positive (or negative) results will have any one particular additional correction positive (or negative). Thus, the probability of any two particular corrections having the same sign is $\frac{1}{2}\times\frac{1}{2}=(\frac{1}{2})^2=\frac{1}{4}$. The probability of all ten corrections having the same sign is $(\frac{1}{2})^{10}=\frac{1}{1024}$. If there were 20 corrections, the probability of all having the same sign would be $(\frac{1}{2})^{20}=\frac{1}{1{,}048{,}576}$.

The standard deviation of the *sum* of such errors is found by squaring each error individually, *adding* the results and taking the square root of the sum. Thus, in the example, the following results are obtained:

Error	*Error Squared*
3	9
2	4
1	1
2	4
4	16
2	4
1	1
8	64
1	1
2	4
sum	108
square root	±10. 4

Thus, the standard deviation is ±10.4. Signs need not be considered because the square of either a positive or negative number is positive.

The individual errors have been treated as if they were fixed in amount. If they are 50 percent normal errors, the result is the standard deviations of the 50 percent errors; if 99 percent, the result is the standard deviations of the 99 percent errors, etc., *if* the individual errors are normal and independent. If they are of a different type, an adjustment is needed. Thus, the square of each rectangular error should be multiplied by the following factors:

50% error ⅔
95% error 1⅔
99% error 2½
99.9% error 4.

The information required to determine the standard deviation is usually not available to a navigator, because the probable magnitude of many of the individual errors has never been determined. However, the example given above reveals at least one interesting point which is highly practical. In the tabulation of errors, the largest has a value of eight. This single error accounts for less than one-third the total *possible* error, but its square is more than half the sum of squares. If this error could be eliminated, the standard deviation would be only 6.6. If it could be reduced to 5, a 37.5 percent reduction, the standard deviation would be reduced to 8.3. In contrast, if the next largest error, four, were reduced by three, a reduction of 75 percent, the standard deviation would be reduced by only 0.8, to 9.6. If the three errors of one each could be completely eliminated, the standard deviation would be reduced by only 0.2, to 10.2. In the reduction of total error, therefore, a relatively small reduction in a large error has a much greater effect upon the standard deviation than the same numerical reduction (larger percentage reduction) in a small error, because the result of a random error is proportional to its square.

Therefore, the perfection of one part of a process, sometimes at great expense or by the introduction of considerable inconvenience, may not be justified until larger errors are corrected. Thus, it would hardly be worth the effort and expense to build a loran receiver capable of making a reading to 0.1 μs (present receivers can be read to about 1 μs) as long as synchronization of signals may be in error as much as 2 μs or more. Conversely, the introduction of an additional small error may add considerably to the convenience of a process without materially affecting the accuracy. Thus, the use of some of the "short" methods of sight reduction (ch. XXI) without interpolation is justified if the interval of tabulation is small.

When both systematic and random errors are present in a process, both effects are present. An increase in the number of readings decreases the residual random error, but regardless of the number of readings, a systematic error is present in its entirety. Thus, if a number of Decca readings are made at a fixed point, the average should be a good approximation of the true value if there is no systematic error. But if the equipment is out of adjustment to the extent that the lane is incorrectly identified, no number of readings will correct this error. In this illustration, a constant error is combined with a normal random error. The normal curve has the correct shape, but is offset from the zero value.

Under some conditions, systematic errors can be eliminated from the results even when the magnitude is not determined. Thus, if two celestial bodies differ in azimuth by 180°, and the altitude of each is observed, the line midway between the lines of position resulting from these observations is free from any *constant* error in the *altitude* (such as abnormal refraction or dip, or incorrect IC). It would *not* be free from such a constant error as one in time (unless the bodies were on the celestial meridian). Similarly, a fix obtained by observations of three stars differing in azimuth by 120°, or four stars differing by 90° is free from constant error in the altitude, if the center of the figure made by the lines of position is used. The center of the figure formed by circles of position from distances of objects equally spaced in azimuth is free from a constant error in range. A constant error in bearing lines does not introduce an error in the fix if the objects are equally spaced in azimuth. In all of these examples, the correct position is *outside* the figure formed by the lines of position if all objects observed are on the same side of the observer (that is, if they lie within an arc of less than 180°).

2906. Most probable position.—Some navigators, particularly those of little experience, have been encouraged by the oversimplified definitions and explanations usually given in texts to conclude that the line of position is infallible, and that a fix is without error, overlooking the frequent incompatibility of these two notions. Too often the idea has prevailed that information is either all right or all wrong. An example is the practice of establishing an estimated position at the foot of the perpendicular from a dead reckoning position, or previous estimated position, to a line of position. The assumption is that the vessel *must* be somewhere on the line of position, and that the only value of the DR position is to locate which point on the line to use as the EP.

A more realistic concept is that of the **most probable position** (**MPP**), which recognizes the probability of error in *all* navigational information, and determines position by an evaluation of all available information, using the principles of errors.

Suppose a vessel were to start from a completely accurate position and proceed on dead reckoning. If course and speed over the bottom were of equal accuracy, the uncertainty of dead reckoning positions would increase equally in all directions with either distance or elapsed time (for any one speed these would be directly proportional and therefore either could be used). Therefore, a circle of uncertainty would grow around the dead reckoning position as the vessel proceeded. If the navigator had full knowledge of the distribution and nature of the errors of course and speed, and the necessary knowledge of statistical analysis, he could compute the radius of the circle of uncertainty, using the 50 percent, 95 percent, or other value of individual errors.

In ordinary navigation, this is not practicable, but based upon his experience and judgment, the navigator might estimate at any time the probable error of his dead reckoning or estimated position. With practice, he might acquire considerable skill in making this estimate. He would take into account, too, the fact that the area of uncertainty might better be represented by an ellipse than a circle, the major axis being along the course line if the probable error of the speed were greater than that of the course, and the minor axis being along the course line if the probable error of the

course were greater. He would recognize, too, that the size of the area of uncertainty would not grow in direct proportion to the distance or elapsed time, because disturbing factors such as wind and current could not be expected to remain of constant magnitude and direction. Also, he would know that the starting point of the dead reckoning would not be completely free from error.

At some future time additional positional information would be obtained. This might be a line of position from a celestial observation or by loran. This, too, would be accompanied by a probable error which might be computed if the necessary information and knowledge were available, but which in practice would be estimated. If the dead reckoning had started from a good position obtained by means of landmarks, the probable error of the initial position would be very small. At first the dead reckoning or estimated position would probably be more reliable than a line of position obtained by celestial observation or loran. But at *some* distance the two would be equal, and beyond this the line of position might be more accurate.

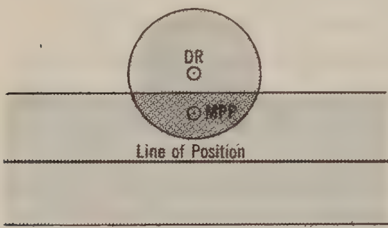

FIGURE 2906a.—A most probable position based upon a dead reckoning position and line of position having equal probable errors.

However, the determination of most probable position does not depend upon determination of *which* information is most accurate. In figure 2906a a dead reckoning position is shown surrounded by a circle of uncertainty. A line of position is also shown, with its area of uncertainty. The most probable position is within the overlapping area, and if the uncertainty of the dead reckoning position and that of the line of position are about equal, it might be taken at the center of the area. If the overall errors are considered normal, and they are probably approximately so, *the effect of each is proportional to its square* (art. 2905). Thus, if the probable error of a dead reckoning position is three miles, and that of a line of position is two miles, the most probable position is nearer the line of position, being at a distance equal to $\frac{2^2}{3^2}=\frac{4}{9}$ that from the dead reckoning position (or $\frac{9}{13}$ of the perpendicular distance from the dead reckoning position to the line of position).

If a fix is obtained from two lines of position, the area of uncertainty is a circle if the lines are perpendicular, have equal probable errors, and these errors can be considered normal. If one is considered more accurate than the other, the area is an ellipse, the two axes being proportional to the *squares* of the two errors. As shown in figure 2906b, it is also an ellipse if the probable error of each is equal and the lines cross at an oblique angle. If the errors are unequal, the major axis of the ellipse is more nearly in line with the line of position having the smaller probable error. If the angle between lines is very small, they are better considered a single line of position in the direction of the major axis of the ellipse.

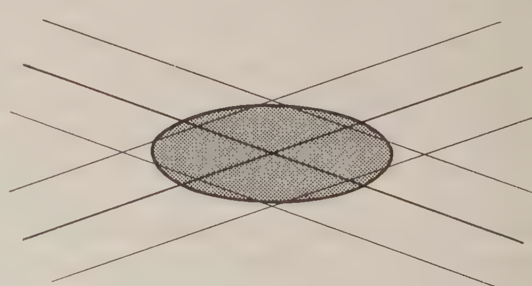

FIGURE 2906b.—Ellipse of uncertainty with lines of position of equal probable errors crossing at an oblique angle.

If a fix is obtained from three or more lines of position, and the error of each line is normal and equal to that of the others, the most probable position is the center of the figure. By "center" is meant that point within the figure which is equidistant from the sides. If the lines are of unequal probable error, the distance of the most

probable position from each line of position is proportional to the *square* of the probable error of that line. Thus, if three lines have probable errors of one, two, and three miles, respectively, the distances of the most probable position from the lines are in the ratio of one, four, and nine, respectively.

In the discussion of most probable position from lines of position, it has been assumed that no other positional information is available. Usually, this is an incorrect assumption, for there is nearly always a dead reckoning or estimated position. This can be considered in any of several ways. The square of its probable error can be used in the same manner as the square of the probable error of each line of position. A most probable position based upon the dead reckoning or estimated position and the most reliable line of position might be determined as explained above, and that line of position replaced with a new one parallel to it but passing through the most probable position just determined. This adjusted line of position can then be assigned a smaller probable error and used with the other lines of position to determine the overall most probable position. A third way is to establish a probable error for the fix, and consider the most probable position as that point along the straight line joining the fix and the dead reckoning or estimated position, the relative distances being equal to the square of the probable error of each position.

The value of the most probable position determined as suggested above depends upon the degree to which the various errors are in fact normal, and the accuracy with which the probable error of each is established. From a practical standpoint, the second factor is largely a matter of judgment based upon experience. It might seem that interpretation of results and establishment of most probable position is a matter of judgment anyway, and that the procedure outlined above is not needed. If a person will follow this procedure while gaining experience, and evaluate his results, the judgment he develops should be more reliable than if developed without benefit of a knowledge of the principles involved. The important point to remember is that the relative effects of normal random errors are proportional to their *squares*.

Systematic errors are treated differently. Generally, an attempt is made to discover the errors and eliminate them or compensate for them. In the case of a position determined by three or more lines of position resulting from readings with constant error, the error might be eliminated by finding and applying that correction (including sign) which will bring all lines through a common point.

2907. Mistakes.—The recognition of a mistake, as contrasted with an error (art. 2902), is not always easy, since a mistake may have any magnitude, and may be either positive or negative. A large mistake should be readily apparent if the navigator is alert and has an understanding of the size of error to be reasonably expected. A small mistake is usually not detected unless the work is checked.

If results by two methods are compared, as a dead reckoning position and a line of position, exact agreement is not to be expected. But if the discrepancy is unreasonably large, a mistake is logically suspected. The definition of "unreasonably large" is a matter of opinion. If the 99.9 percent areas of the two results just touch, it is *possible* that no mistake has been made. However, the *probability* of either one having so great an error is remote if the errors are normal. The probability of both having 99.9 percent error of opposite sign at the same instant is very small indeed. Perhaps a reasonable standard is that unless the most accurate result lies within the 95 percent area of the least accurate result, the possibility of a mistake should be investigated. Thus, if the areas of uncertainty shown in figure 2906a represent the 95 percent areas, it is probable that a mistake has been made.

As in other matters pertaining to navigation, judgment is important. The use to be made of the results is certainly a consideration. In the middle of an ocean pas-

sage a mistake is usually not serious, and will undoubtedly be corrected before it jeopardizes the safety of the vessel. But if landfall is soon to be made, or if search and rescue operations are to be based upon the position, almost any mistake is intolerable.

2908. Miscellaneous.—The correct identification of the nature of an error is important if the error is to be handled intelligently. Thus, the statement is sometimes made that a radio bearing need not be corrected if the receiver is within 50 miles of the transmitter. The need for a correction arises from the fact that radio waves are assumed to follow great circles, and if radio bearings are to be plotted on a Mercator chart, the equivalent rhumb line is needed. The statement regarding 50 miles implies that the size of the correction is proportional to distance only. It overlooks the fact that latitude and direction of the bearing line are also important factors, and is therefore a dangerous statement unless its limitations are understood.

The recognition of the type of error is also important. A systematic error has quite a different effect than a random error, and cannot be reduced by additional readings unless some method or procedure is instituted which will cause the errors to cancel each other. If a position is subject to a rectangular error only, its 100 percent circle has twice the radius and four times the area of the 50 percent circle. But if the error is normal, the 95 percent circle has approximately three times the radius and *nine* times the area of the 50 percent circle. It is not correct to suppose that a craft is as likely to be at one point within a circle of uncertainty as at any other point. If the error is normal, the probability might be represented by a three-dimensional figure formed by rotating the normal curve (fig. 2904a) around its axis of symmetry.

The probable error is usually of greater interest than the "average" value. The average of a large number of normal errors approaches zero, but the probable error might be quite large. An average or mean value determined by a number of observations is sometimes given with its probable error. Thus, a person might make a number of measurements of the speed of light and state his results as $299{,}792 \pm 2$ kilometers per second.

A person who understands the nature of errors avoids many pitfalls. Thus, the magnitude of the errors of individual lines of position is not a reliable indication of the size of the error of the fix obtained from them. The size of the triangle formed by three lines of position has often been used as a guide to the accuracy of the fix, although a large triangle might be the result of a large constant error if the objects observed are equally spaced in azimuth. On the other hand, two lines of position with small errors might produce a fix having a much larger error if the lines cross at a small angle.

The size of a triangle of position might be deceptive for another reason. A constant error in time shifts all lines of position from celestial observation an approximately equal amount (in minutes of arc) toward the east or toward the west. If all objects observed for a fix are on the same side of the observer, a constant error in measurement shifts all objects *and the fix*, so that if the constant error is larger than the random error, the actual position is outside the figure formed by the lines of position.

OCEANOGRAPHY

PART SIX

OCEANOGRAPHY

CHAPTER XXX

THE OCEANS

3001. Introduction.—**Oceanography** is the application of the sciences to the phenomena of the oceans. It includes a study of their forms; physical, chemical, and biological features; and phenomena. Thus, it embraces the widely separated fields of geography, geology, chemistry, physics, and biology. Many subdivisions of these sciences, such as sedimentation, ecology (biological relationship between organisms and their environment), bacteriology, biochemistry, hydrodynamics, acoustics, and optics, have been extensively studied in the oceans.

The oceans cover 70.8 percent of the surface of the earth. The Atlantic covers 16.2 percent, the Pacific 32.4 percent (3.2 percent more than the land area of the entire earth), the Indian Ocean 14.4 percent, and marginal and adjacent areas (of which the largest is the Arctic Ocean) 7.8 percent. Their extent alone makes them an important subject for study. However, greater incentive lies in their use for transportation, their influence upon weather and climate, and their potentiality as a source of power, food, fresh water, and mineral and organic substances.

3002. History of oceanography.—The earliest studies of the oceans were concerned principally with problems of navigation. Information concerning tides, currents, soundings, ice, and distances between ports was needed as ocean commerce increased. According to Posidonius, a depth of 1,000 fathoms had been measured in the Sea of Sardinia as early as the second century BC. About the middle of the 19th century, the Darwinian theories of evolution gave a great impetus to the collection of marine organisms, since it is believed by some that all terrestrial forms have evolved from oceanic ancestors. Later, the serious depletion of many fisheries called for investigation of the relation of the economically valuable organisms to the physical characteristics of their environment, especially in northwestern Europe and off Japan. Still later, the growing use of the oceans in warfare, particularly after the development of the submarine, required that much effort be expended in problems of detection and attack, resulting in the study of many previously neglected scientific aspects of the sea.

Oceanographic exploration. Exploration of the seas was primarily geographical until the 19th century, although the accumulated observations of seafarers, as recorded in the early charts and sailing directions, often included data on tides, currents, and other oceanographic phenomena. The great voyages of discovery, particularly those beginning in 1768 with Captain Cook, and continued by such commanders as La Pérouse, Bellingshausen, and Wilkes, included scientists in their complements. However, scientific work on the oceans at this period was severely limited by lack of suitable instruments for probing conditions below the surface. Meanwhile, Lieutenant Matthew Fontaine Maury, USN, working in the forerunner of the U. S. Navy Hydrographic Office in Washington, developed to a high degree of perfection the analysis of log-book observations. His first results, published in 1848, were of great importance to ship operations in the recommendation of favorable sailing routes, and they stimulated international cooperation in the fields of oceanography and marine meteorology.

In the rapid advances in technology after 1850, oceanographic instrumentation problems were not neglected, with the result that the British Navy in 1872–76 was able to send HMS *Challenger* around the world on the first purely deep-sea oceano-

graphic expedition ever attempted. Her bottom samples, as analyzed by Sir John Murray, laid the foundation of geological oceanography, and 77 of her sea water samples, analyzed by C. R. Dittmar, proved for the first time that various constituents of the salts in sea water are everywhere in virtually the same proportions.

Since that time, the coastal waters and fishing banks of many nations have been extensively studied, and numerous vessels of various nationalities have conducted work on the high seas. Notable among these have been the American *Albatross* from 1882 to 1920; the Austrian *Pola* in the Mediterranean and Red Seas between 1890 and 1896; the Danish *Dana*, which during its voyages of 1920–22 discovered the breeding place of the European eels in the Sargasso Sea; the American *Carnegie* in 1927–29; the German *Meteor* in the Atlantic from 1928 to 1938; and the British *Discovery II* in the antarctic between 1930 and 1939. Notable also were the drifts of the Norwegian vessels *Fram* and *Maud* in the arctic ice pack from 1893 to 1896 and 1918 to 1925, respectively; the attempt by Sir George Hubert Wilkins to operate under the ice in the British submarine *Nautilus* in 1931; and the Russian station set up at the north pole in 1937, which made observations from the drifting pack ice.

At the same time, investigations pursued ashore provided the theoretical basis for the explanation of ocean currents, under the leadership of Helland-Hansen in Norway and Ekman and the Bjerknes in Sweden, while Martin Knudsen in Denmark worked out the precise details of the relationship between chlorinity, salinity, and density, enabling the theories to be verified by field observations.

During World War II, basic investigations were interrupted while work on purely military applications of oceanography was carried out. Deep-sea expeditions were renewed by the Swedish *Albatross* after the war, followed by the Danish *Galathea*, the second British *Challenger* (built in 1931) and *Discovery II* in the antarctic, and vessels of the American Scripps Institution in the Pacific. Oceanographic work was carried out by Americans and Russians in the arctic. By 1961, a total of ten Russian and three United States drifting ice stations had been established. Two United States stations were also established aboard floating ice islands.

Institutions. Among the leading oceanographic institutions in Europe are the Geophysical Institute of the University of Bergen in Norway; the Oceanographic Institute at Göteborg, Sweden; the National Institute of Oceanography in Great Britain; the German Hydrographic Institute in Hamburg; and the Museum of Oceanography at Monaco. The Marine Biological Station at Naples, Italy, has served as a model for others throughout the world.

In the Far East, the Hydrographic Division of the Maritime Safety Agency is perhaps the most prominent of a number of Japanese oceanographic activities. The Institute of Oceanology at Vladivostok is the foremost oceanographic establishment on the Asiatic mainland.

Canada maintains the Pacific Oceanographic Group at Nanaimo, B. C., and the Atlantic Oceanographic Group at St. Andrews, N. B. In the United States, the leading nongovernmental oceanographic institutions include the Scripps Institution of Oceanography of the University of California, La Jolla, Calif.; the Department of Oceanography of the University of Washington, Seattle, Wash.; Woods Hole Oceanographic Institution, Woods Hole, Mass.; the Marine Laboratory of the University of Miami, Coral Gables, Fla.; and the Department of Oceanography of Texas A. & M. College, College Station, Tex.

There exist also various international organizations in the field of oceanography, which coordinate and promote international cooperation. The International Council for the Exploration of the Sea, with headquarters in Copenhagen, which was established

to exchange data on fisheries problems in the waters of northwestern Europe, has been notably successful, and similar organizations have been established in other areas.

3003. Origin of the oceans.—Although many leading geologists still disagree with the conclusion that the structure of the continents is fundamentally different from that of the oceans, there is a growing body of evidence in support of the theory that the rocks underlying the ocean floors are more dense than those underlying the continents. According to this theory, all the earth's crust floats on a central liquid core, and the portions that make up the continents, being lighter, float with a higher freeboard. Thus, the thinner areas, composed of heavier rock, form natural basins where water has collected.

The origin of the water in the oceans is also controversial. Although some geologists have postulated that all the water existed as vapor in the atmosphere of the primeval earth, and that it fell in great torrents of rain as soon as the earth cooled sufficiently, another school holds that the atmosphere of the original hot earth was lost, and that the water gradually accumulated as it was given off in steam by volcanoes or worked to the surface in hot springs.

Most of the water on the earth's crust is now in the oceans—about 328,000,000 cubic statute miles, or about 85 percent of the total. The mean depth of the ocean is 2,075 fathoms, and the total area is 139,000,000 square statute miles.

3004. Oceanographic chemistry may be divided into three main parts: the chemistry of (1) sea water, (2) marine sediments, and (3) organisms living in the sea. The first is of particular interest to the navigator.

Chemical properties of sea water are determined by analyzing samples of water obtained at various places and depths. Samples from below the surface are obtained by means of metal bottles designed for this purpose. The open bottles are attached at suitable intervals to a wire lowered into the sea. When they reach the desired depths, a metal ring or **messenger** is dropped down the wire. When the messenger arrives at the first bottle, it causes the bottle to close, trapping a sample of the water at that depth, and releasing a second messenger which travels on down the wire. The process is repeated at each bottle until all are closed, when they are hauled up and each bottle detached as it comes within reach. Of the various types devised, the **Nansen bottle** is the most widely used. It is equipped with a removable frame for attaching a thermometer.

For centuries table salt has been produced from sea water by natural evaporation in countries with a suitable climate. More recently, practical industrial processes have been developed for recovering bromine and magnesium from the sea. Calcium carbonate, in the form of oyster shells or coral rock, is obtained after precipitation by living organisms.

Three elements in the sea, silicon, nitrogen, and phosphorus, are most significant in the growth of living organisms.

Certain of the elements, notably chlorine, bromine, sulfur, and boron, are much more abundant in the ocean than in the rest of the earth's crust. These elements are among the more volatile ones, and their abundance in the sea tends to confirm the hypothesis that volcanic action is largely responsible for the present oceans.

In many cases, chemical relationships influence the abundance of elements in the sea. Barium, for example, forms a sulfate of very limited solubility, and thus the high concentration of sulfate in sea water limits the possible amount of dissolved barium. Thus, the concentration of many elements is limited by the solubility of their most insoluble compounds. Table 3004 indicates the amounts of the various elements found in solution in the oceans.

In addition to dissolved solids, sea water contains in solution all of the gases found in the atmosphere (art. 1410), but not in the same proportions. The most abundant is nitrogen, which, however, because of its chemical inertness, does not enter into biological processes. Oxygen, produced in the surface layers by plant photosynthesis (art. 3024) or dissolved directly from the atmosphere, is of major importance for all forms of life. By biological activity, the oxygen concentration at depths below the surface is usually reduced to a fraction of the surface values, and under certain conditions, owing either to the presence of abundant oxidizable material, or a stagnant condition, or both, it may become completely exhausted. Under these conditions, sulfate-reducing bacteria produce hydrogen sulfide gas from the abundant sulfate in sea water. The existence of such conditions is often indicated to the mariner by the blackening of white lead paint, a well-known phenomenon in badly polluted estuaries.

Hydrogen sulfide may also be encountered at great depths in the ocean. The fiords of Norway, deep channels cut by former glaciers, are characterized in general by shallow sills at the entrances, where the terminal moraines of the glaciers were deposited. These sills serve as barriers to the mixing and renewing of the deeper waters within the fiords, and, as a result, conditions producing hydrogen sulfide are frequently encountered.

Element	Parts per million	Element	Parts per million
Aluminum	0. 01	Manganese	0. 001–0. 01
Arsenic	0. 003	Mercury	0. 00003
Barium	0. 006	Molybdenum	0. 01
Boron	4. 7	Nickel	0. 0005
Bromine	66	Nitrogen	0. 01–0. 7
Cadmium	0. 00006	Phosphorus	0. 001–0. 1
Calcium	408	Potassium	387
Carbon	28	Radium	0. 00000000003
Cerium	0. 0004	Rubidium	0. 3
Cesium	0. 001	Scandium	0. 00004
Chlorine	19, 353	Selenium	0. 004
Chromium	0. 00005	Silicon	0. 02–4. 0
Cobalt	0. 0005	Silver	0. 0003
Copper	0. 001–0. 01	Sodium	10, 769
Fluorine	1. 4	Strontium	10
Gallium	0. 0005	Sulfur	901
Gold	0. 000004	Thorium	0. 0007
Iodine	0. 05	Tin	0. 003
Iron	0. 002–0. 02	Titanium	0. 001
Lanthanum	0. 0003	Uranium	0. 0033
Lead	0. 003	Vanadium	0. 001
Lithium	0. 2	Yttrium	0. 0003
Magnesium	1, 297	Zinc	0. 01

TABLE 3004.—Elements found in solution in the ocean. The amounts are for a salinity of 35 parts per thousand. These values are based upon a tabulation by Professor E. D. Goldberg of the Scripps Institution of Oceanography.

A similar situation exists in the Black Sea. Here the Bosporus and Dardanelles act as sills, and all the deeper water of the Black Sea is cut off from contact with the surface waters, which, diluted by the runoff from the Danube and Don Rivers, have a salinity (art. 3006) of about 17.5 parts per thousand. The deeper water, renewed only by the bottom current through the Bosporus, has a salinity of 22 parts per thousand, and the great density difference between the surface layers and the deeper water effectively prevents mixing and the transfer of dissolved oxygen from the surface layers to greater depths. Below about 100 fathoms, therefore, the waters of the Black Sea are

completely devoid of dissolved oxygen, containing instead large concentrations of hydrogen sulfide.

No living creatures exist under these conditions except anaerobic bacteria, which comprise the only form of life in five-sixths of the waters of the Black Sea.

3005. Physical properties of sea water are dependent primarily upon salinity, temperature, and pressure. However, factors like motion of the water and the amount of suspended matter affect such properties as color and transparency, conduction of heat, absorption of radiation, etc.

3006. Salinity is the amount of dissolved solid material in the water, usually expressed as parts per thousand (by weight), under certain standard conditions. This is not the same as **chlorinity,** which is equal approximately to the amount of chlorine in the water. (Actually the chlorine content is about 1.00045 times the chlorinity as determined by standard procedures.) The two have been found to be related empirically by the formula

$$\text{salinity} = 0.03 + 1.805 \times \text{chlorinity}.$$

Since the determination of salinity is a slow and difficult process, while chlorinity can be determined easily and accurately by titration with silver nitrate, it is customary to determine chlorinity and compute salinity by the formula given above. By this process, salinity can be determined with an error not exceeding 0.02 parts per thousand. It generally varies between about 33 and 37 parts per thousand, the average being about 35 parts per thousand. However, when the water has been diluted, as near the mouth of a river or after a heavy rainfall, the salinity is somewhat less; and in areas of excessive evaporation, the salinity may be as high as 40 parts per thousand. In certain confined bodies of water, notably the Great Salt Lake in Utah, and the Dead Sea in Asia Minor, the salinity is several times this maximum. Chlorinity accounts for about 55 percent of salinity, the average being about 19 parts per thousand.

3007. Temperature in the ocean varies widely, both horizontally and with depth. Maximum values of about 90° F are encountered in the Persian Gulf in summer, and the lowest possible values of about 28° F (the usual minimum freezing point of sea water) occur in polar regions. H.O. Pub. No. 225, *World Atlas of Sea Surface Temperatures,* shows in detail the average sea surface temperatures for each month. The following tabulation gives the percentage distribution of temperatures for the world for the months of February and August, as derived from this source:

Surface temperature ° F	*Percentage of area of ocean February*	*August*
<35	12. 0	13. 1
35–40	6. 5	3. 3
40–45	4. 0	3. 0
45–50	4. 5	5. 0
50–55	4. 0	6. 5
55–60	5. 0	6. 0
60–65	5. 5	6. 3
65–70	8. 0	7. 0
70–75	10. 0	10. 4
75–80	17. 5	16. 5
80–85	23. 0	22. 7
85–90	0. 0	0. 2

The vertical distribution of temperature in the sea nearly everywhere shows a decrease of temperature with depth. Since colder water is denser, it sinks below warmer

water. This results in a temperature distribution just opposite to that in the earth's crust, where temperature increases with depth below the surface of the ground.

In general, in the sea there is usually a mixed layer of isothermal water below the surface, where the temperature is the same as that of the surface. This layer is best developed in the trade-wind belts, where it may extend to a depth of 100 fathoms; in temperate latitudes in the spring, it may disappear entirely. Below this layer is a zone of rapid temperature decrease, called the **thermocline,** to the temperature of the deep oceans. At a depth greater than 200 fathoms, the temperature everywhere is below 60°F, and in the deeper layers, fed by cooled waters that have sunk from the surface in the arctic and antarctic, temperatures as low as 33°F exist.

In the deepest ocean basins, the temperature increases slightly with depth, the increase being about 1°F at 3,000 fathoms. The warming is believed to be caused more by the slight compression of sea water than by heat from the earth's crust.

A typical curve of temperature at various depths is shown in figure 3503a. Temperature at any desired depth is determined by means of a **reversing thermometer** attached to a Nansen bottle (art. 3004). When the bottle closes, the thermometer measures the temperature to within 0°.04 F, thus providing a reading for a particular time and point. Within about 75 fathoms of the surface, where the principal changes occur, a continuous record of temperature can be obtained by an instrument called a **bathythermograph,** invented by Spilhaus in 1938.

3008. Pressure.—In oceanographic work, pressure is generally expressed in units of the centimeter-gram-second system. The basic unit of this system is one dyne per square centimeter. This is a very small unit, one million constituting a practical unit called a bar, which is nearly equal to one atmosphere. Atmospheric pressure is often expressed in terms of **millibars,** 1,000 of these being equal to one bar. In oceanographic work, water pressure is commonly expressed in terms of **decibars,** ten of these being equal to one bar. One decibar is equal to nearly 1½ pounds per square inch. This unit is convenient because it is very nearly the pressure exerted by one meter of water. Thus, the pressure in decibars is approximately the same as the depth in meters, the unit of depth customarily used in oceanographic research. In terms more familiar to the mariner, the pressure at various depths is as follows:

Depth in fathoms	*Pressure in pounds per square inch*
1, 000	2, 680
2, 000	5, 390
3, 000	8, 100
4, 000	10, 810
5, 000	13, 520

The increase in pressure with depth is nearly constant because water is only slightly compressible.

Although virtually all of the physical properties of sea water are affected to a measurable extent by pressure, the effect is not as great as those of salinity and temperature. Pressure is of particular importance to submarines, directly because of the stress it induces in the materials of the craft, and indirectly because of its effect upon buoyancy.

3009. Density is mass per unit volume. Oceanographers use the centimeter-gram-second system, in which density is expressed as grams per cubic centimeter. The ratio of the density of a substance to that of a standard substance under stated conditions is called **specific gravity.** By definition, the density of distilled water at 4°C (39°.2 F) is one gram per milliliter (approximately one gram per cubic centimeter).

Therefore, if this is used as the standard, as it is in oceanographic work, density and specific gravity are virtually identical numerically.

The density of sea water depends upon salinity, temperature, and pressure. At constant temperature and pressure, density varies with salinity or, because of the relationship between this and chlorinity, with the chlorinity. A temperature of 32° F and atmospheric pressure are considered standard for density determination. The effects of thermal expansion and compressibility are used to determine the density at other temperatures and pressures. The density at a particular pressure affects the buoyancy of submarines. It is also important in its relation to ocean currents.

The greatest changes in density of sea water occur at the surface, where the water is subject to influences not present at depths. Here density is decreased by precipitation, run-off from land, melting of ice, or heating. When the surface water becomes less dense, it tends to float on top of the more dense water below. There is little tendency for the water to mix, and so the condition is one of stability. The density of surface water is increased by evaporation, formation of sea ice, and by cooling. If the surface water becomes more dense than that below, it sinks to the level at which other water has the same density. Here it tends to spread out to form a layer, or to increase the thickness of the layer below it. The less dense water rises to make room for it, and the surface water moves in to replace that which has descended. Thus, a convective circulation is established. It continues until the density becomes uniform from the surface to the depth at which a greater density occurs. If the surface water becomes sufficiently dense, it sinks all the way to the bottom. If this occurs in an area where horizontal flow is unobstructed, the water which has descended spreads to other regions, creating a dense bottom layer. Since the greatest increase in density occurs in polar regions, where the air is cold and great quantities of ice form, the cold, dense polar water sinks to the bottom and then spreads to lower latitudes. This process has continued for a sufficiently long period of time that the entire ocean floor is covered with this dense polar water, thus explaining the layer of cold water at great depths in all the oceans.

In some respects, oceanographic processes are similar to those occurring in the atmosphere (ch. XXXVIII). The convective circulation in the ocean is somewhat similar to that in the atmosphere. Water masses having nearly uniform characteristics are analogous to air masses.

3010. Compressibility.—Sea water is nearly incompressible, its coefficient of compressibility being only 0.000046 per bar under standard conditions. This value changes slightly with changes of temperature or salinity. The effect of compression is to force the molecules of the substance closer together, causing it to become more dense. Even though the compressibility is low, its total effect is considerable because of the amount of water involved. If the compressibility of sea water were zero, sea level would be about 90 feet higher than it now is.

3011. Viscosity is resistance to flow. Sea water is slightly more viscous than fresh water. Its viscosity increases with greater salinity, but the effect is not nearly as marked as that occurring with decreasing temperature. The rate is not uniform, becoming greater as the temperature decreases. Because of the effect of temperature upon viscosity, an incompressible object might sink at a faster rate in warm surface water than in colder water below. However, for most objects, this effect may be more than offset by the compressibility of the object.

The actual relationships existing in the ocean are considerably more complicated than indicated by the simple explanation given above, because of turbulent motion within the sea. The disturbing effect is called **eddy viscosity.**

3012. Specific heat is the amount of heat required to raise the temperature of a unit mass of a substance a stated amount. In oceanographic work, specific heat is stated, in centimeter-gram-second units, as the number of calories needed to raise one gram of the substance 1°C. Specific heat at constant pressure is usually the quantity desired when liquids are involved, but occasionally the specific heat at constant volume is required. The ratio of these two quantities has a direct relationship to the speed of sound in sea water.

The specific heat of sea water decreases slightly as salinity increases. However, it is much greater than that of land. This accounts, in part, for the greater temperature range of land and the atmosphere above it, resulting in monsoons (art. 3810) and the familiar land and sea breezes of tropical and temperate regions (art. 3814).

3013. Thermal expansion.—The rate of expansion with increased temperature is greater in sea water than in fresh water. Thus, at temperature 15°C (59°F), and atmospheric pressure, the coefficient of thermal expansion is 0.000151 per degree Celsius for fresh water and 0.000214 per degree Celsius for water of 35 parts per thousand salinity. The coefficient of thermal expansion increases not only with greater salinity, but also with increased temperature and pressure. At 35 parts per thousand, the coefficient of surface water increases from 0.000051 per degree Celsius at 0°C (32°F) to 0.000334 per degree Celsius at 30°C (86°F). At a constant temperature of 0°C (32°F) and a salinity of 34.85 parts per thousand, the coefficient increases to 0.000276 per degree Celsius at a pressure of 10,000 decibars (at a depth of approximately 10,000 meters).

3014. Thermal conductivity.—In water, as in other substances, one method of heat transfer is by conduction. Fresh water is a poor conductor of heat, having a coefficient of thermal conductivity of 0.00139 calories per second per centimeter per degree Celsius. For sea water it is slightly less but increases with greater temperature or pressure.

However, if turbulence is present, which it nearly always is to some extent in the ocean, the processes of heat transfer are altered. The effect of turbulence is to increase greatly the rate of heat transfer. The "eddy" coefficient used in place of the still-water coefficient is so many times larger, and so dependent upon the degree of turbulence that the effects of temperature and pressure are not important.

3015. Electrical conductivity.—Water without impurities is a very poor conductor of electricity. However, when salt is in solution in water, the salt molecules are ionized (art. 1007) and therefore are carriers of electricity. Hence, the electrical conductivity of sea water is directly proportional to the number of salt molecules in the water. For any given salinity, the conductivity increases with an increase in temperature.

3016. Radioactivity.—Although the amount of radioactive material in sea water (tab. 3004) is very small, this material is present in marine sediments to a greater extent than in the rocks of the earth's crust. This is probably due to precipitation of radium or other radioactive material from the water. The radioactivity of the top layers of sediment is less than that of deeper layers. This may be due to absorption of radioactive material in the soft tissues of marine organisms.

3017. Refractive index (art. 1613) of sea water increases as salinity becomes greater, or as temperature decreases. Since it varies with frequency of the radiant energy, the "D line" of sodium is usually used as the standard for comparison.

3018. Surface tension of water in dynes per square centimeter is approximately equal to $75.64-0.144T+0.0399Cl$, where T is temperature in degrees Celsius (centigrade) and Cl is the chlorinity of the water in parts per thousand. As indicated by the last term, the surface tension increases with chlorinity, and is therefore a little

more for sea water than for fresh water. However, the presence of impurities causes it to be somewhat less than indicated by the formula.

3019. Transparency of sea water varies with the number, size, and nature of particles suspended in the water, as well as with the nature and intensity of illumination. The rate of decrease of light energy with depth is called the "extinction coefficient." The earliest method of measuring transparency was by means of a **Secchi disk,** a white disk 30 centimeters (a little less than one foot) in diameter. This was lowered into the sea, and the depth at which it disappeared was recorded. In coastal waters the depth varies from about 5 to 25 meters (16 to 82 feet). Offshore, the depth is usually about 45 to 60 meters (148 to 197 feet). The greatest recorded depth at which the disk has disappeared is 66 meters (217 feet), in the Sargasso Sea.

Although the Secchi disk still affords a simple method of measuring transparency, more exact methods have been devised.

3020. Color.—The color of sea water varies considerably. Water of the Gulf Stream is a deep indigo blue, while a similar current off Japan was named Kuroshio (Black Stream) because of the dark color of its water. Along many coasts the water is green. In certain localities a brown or brownish-red water has been observed.

Offshore, some shade of blue is common, particularly in tropical or sub-tropical regions. It is due to scattering of sunlight by minute particles suspended in the water, or by molecules of the water itself. Because of its short wave length, blue light is more effectively scattered than light of longer waves. Thus, the ocean appears blue for the same reason that the sky does (art. 3817). The green color often seen near the coast is a mixture of the blue due to scattering of light and a stable soluble yellow pigment associated with phytoplankton (art. 3024). Brown or brownish-red water receives its color from large quantities of certain types of **algae,** microscopic plants in the sea.

3021. Marine geology is a branch of oceanography dealing with bottom relief, particularly the characteristics of ocean basins and the geological processes that brought them into being and tend to alter them, as well as with marine sediments.

3022. Bottom relief.—Compared to land, relatively little is known of relief below the surface of the sea. It would be difficult to withhold knowledge of a major land feature in an area often visited by man, but the sea has until recent years proved an effective barrier to acquisition of knowledge of features below its surface. Although soundings of 1,000 fathoms were probably made as early as the second century BC (art. 3002), the number of deep sea soundings by means of a weight lowered to the bottom has been relatively few. The process is a time-consuming one requiring special equipment. Several hours are needed for a single sounding. Since the development of an effective echo sounder (art. 619) in 1922, the number of deep sea soundings has greatly increased. Later, a recording echo sounder was developed to permit the continuous tracing of a **bottom profile.** This has assisted materially in the acquisition of knowledge of bottom relief. By this means, many flat-topped seamounts (called **guyots**), mountain ranges, and other features have been discovered. Although the main features are becoming known, a great many details are yet to be learned.

Along most of the coasts of the continents, the bottom slopes gradually downward to a depth of about 100 fathoms or somewhat less, where it falls away more rapidly to greater depths. This **continental shelf** averages about 30 miles in width, but varies from nothing to about 800 miles, the widest part being off the Siberian arctic coast. A similar shelf extending outward from an island or group of islands is called an **insular shelf.** At the outer edge of the shelf, the steeper slope of 2° to 4° is called the **conti-**

nental talus or **continental slope,** or the **insular talus** or **insular slope,** according to whether it surrounds a continent or group of islands. The shelf itself is not uniform, but has numerous hills, ridges, terraces, and canyons, the largest being comparable in size to the Grand Canyon.

As a general rule, the slope of the deep sea bottom is gradual, averaging between 20′ and 40′, but there are many exceptions to this. Off a volcanic island it may be as much as 45°. The relief of the ocean floor is comparable to that of land. Both have steep, rugged mountains, deep canyons, rolling hills, plains, etc. Most of the ocean floor is considered to be made up of a number of more-or-less circular or oval depressions called **basins,** surrounded by walls of lesser depth.

The average depth of water in the oceans is 2,075 fathoms (12,450 feet), as compared to an average height of land above the sea of about 2,750 feet. The greatest known depth is 35,640 feet, in the Marianas Trench in the Pacific. The highest known land is Mount Everest, 29,002 feet. About 23 percent of the ocean is shallower than 10,000 feet, about 76 percent is between 10,000 and 20,000 feet, and a little more than one percent is deeper than 20,000 feet. A very deep part, generally that below 3,000 fathoms, is called a **deep.** A long, narrow depression with steep sides is called a **trench.**

3023. Marine sediments.—The ocean floor is composed of material deposited there through the years. This material consists principally of (1) earth and rocks washed into the sea by streams and waves, (2) volcanic ashes and lava, and (3) the remains of marine organisms. Lesser amounts of land material are carried into the sea by glaciers, or blown out to sea by wind. In the ocean, the material is transported by ocean currents, waves, and ice. Near shore the material is deposited at the rate of about three inches in 1,000 years, while in the deep water offshore the rate is only about half an inch in 1,000 years. Marine deposits in water deep enough to be relatively free from wave action are subject to little erosion. Because of this and the slow rate of deposit, marine sediments provide a better geological record than does the land.

Marine sediments are composed of individual particles of all sizes from the finest clay to large boulders. In general, the inorganic deposits near shore are relatively coarse (sand, gravel, shingle, etc.), while those in deep water are much finer (clay). In some areas the siliceous remains of marine organisms or the calcareous deposits (of either organic or inorganic origin) are sufficient to predominate on the ocean floor.

A wide range of colors is found in marine sediments. The lighter colors (white or a pale tint) are usually associated with coarse-grained quartz or limestone deposits. Darker colors (red, blue, green, etc.) are usually found in mud having a predominance of some mineral substance, such as an oxide of iron or manganese. Black mud is often found in an area that is little disturbed, such as at the bottom of an inlet or in a depression without free access to other areas.

Marine sediments are studied primarily by means of bottom samples. Samples of surface deposits are obtained by means of a **snapper** (for mud, sand, etc.) or "dredge" (usually for rocky material). If a sample of material below the bottom surface is desired, a "coring" device is used. This device consists essentially of a tube driven into the bottom by weights or explosives. A sample obtained in this way preserves the natural order of the various layers. Samples of more than 100 feet in depth have been obtained by means of coring devices. The bottom sample obtained by the mariner, by arming his lead with tallow or soap (art. 617), is an incomplete indication of bottom surface conditions.

3024. Marine biology.—Sea water has all of the chemical elements needed to sustain plant and animal life. Because of this, and the fact that the oceans contain about 300 times as much space for the existence of life as is available on land and in fresh water, organic material is present in vast quantities.

Marine life may be divided into three major groups: (1) **nekton** (strong-swimming animals such as fish), (2) **plankton** (tiny floating plants or feebly swimming or floating animals), and (3) **benthos** (plants and animals living on the bottom, such as seaweed, barnacles, and crabs). Plankton may be divided into: (a) the **phytoplankton**, consisting of microscopic floating plants; and (b) the **zooplankton**, consisting of feebly swimming or floating animals. Most plankton vary in size from microscopic units to those a small fraction of an inch in length.

Most organic material in the sea is in the form of plankton, which is carried by the ocean currents, not having sufficient strength to choose its environment. Either directly or indirectly, nearly all marine life depends upon these organisms. By means of **photosynthesis,** a process using sunlight, phytoplankton changes chemical nutrients (silicates, nitrates, phosphates) in the sea into primary food which is used by the zooplankton and, to some extent, by larger animals. However, most of the larger animals feed upon the zooplankton. The chemical nutrients are replaced by the excretion of animals and bacterial action in the decomposition of dead plants and animals. Thus, a food cycle is continually going on from chemical nutrient to phytoplankton to zooplankton to nekton and benthos to chemical nutrients.

As indicated above, growth of phytoplankton requires both sunlight and a supply of chemical nutrients. Sunlight in sufficient strength to permit photosynthesis penetrates to a maximum depth of about 500 feet or less. This upper layer in which the process occurs is called the **euphotic zone.** Within this zone, photosynthesis is limited primarily by the supply of chemical nutrients. Under favorable conditions, phytoplankton may increase by as much as 300 percent in a single day.

The abundance of marine life is directly related to the supply of phytoplankton. In shallow water, the chemical nutrients on the bottom are stirred up by motion of the water, and carried into the euphotic zone. This is why an area such as the Grand Banks is a good fishing ground. In polar regions the chemical nutrients are relatively abundant, being brought to the surface by convective currents as the cold surface water sinks and is replaced by the warmer water from the bottom. In the tropics, on the other hand, the sea is relatively stable, and the chemical nutrients have a tendency to sink below the euphotic zone. Even though the clear, blue water has the deepest euphotic zone, photosynthesis proceeds at a slow rate. For this reason blue is sometimes called the "desert color of the sea."

Ocean currents and marine life are so interrelated that currents can sometimes be traced by their supply of plankton. In general, the oceanic circulation helps sustain marine life by stirring up the chemical nutrients and carrying them, or the plankton formed from them, into regions which have an inadequate supply. However, the reverse effect can occur. A notable example occurs from time to time off the west coast of South America. At varying intervals averaging about 12 years, a well-developed stream of tropical water having a relatively small supply of chemical nutrients and plankton flows southward, close to the shore. This water replaces the colder water which is rich in chemical nutrients and plankton. The result is a wholesale destruction of fish which cannot obtain a sufficient supply of food. In some areas the dead fish are washed ashore in such quantities as to constitute a serious problem. With the destruction of so many fish, the supply of guano also decreases because of the death of large numbers of the birds which depend upon the fish for their food supply. Since it commonly occurs near Christmas, this phenomenon is called "El Niño." A strong current such as the Gulf Stream annually carries many fish to their deaths by transporting them from their normally warm habitat to areas where they encounter water which is too cold for them to endure.

CHAPTER XXXI

TIDES AND TIDAL CURRENTS

General

3101. The tidal phenomenon is the periodic motion of the waters of the sea due to differences in the attractive forces of various celestial bodies, principally the moon and sun, upon different parts of the rotating earth. It can be either a help or hindrance to the mariner—the water's rise and fall may at certain times provide enough depth to clear a bar and at others may prevent him from entering or leaving a harbor. The flow of the current may help his progress or hinder it, may set him toward dangers or away from them. By understanding this phenomenon and by making intelligent use of predictions published in tide and tidal current tables and of descriptions in sailing directions, the mariner can set his course and schedule his passage to make the tide serve him, or at least to avoid its dangers.

3102. Tide and current.—In its rise and fall, the tide is accompanied by a periodic horizontal movement of the water called **tidal current.** The two movements, tide and tidal current, are intimately related, forming parts of the same phenomenon brought about by the tide-producing forces of the sun and moon, principally.

It is necessary, however, to distinguish clearly between tide and tidal current, for the relation between them is not a simple one nor is it everywhere the same. For the sake of clearness and to avoid misunderstanding, it is desirable that the mariner adopt the technical usage: **tide** for the vertical rise and fall of the water, and **current** for the horizontal flow. The tide rises and falls, the tidal current floods and ebbs. In British usage, tidal current is called **tidal stream.**

3103. Cause.—Tides result from differences in the gravitational attraction of various celestial bodies, principally the moon and sun, upon different parts of the rotating earth. The gravity of the earth acts approximately toward the earth's center, and tends to hold the earth in the shape of a sphere. But the moon and sun provide disturbing, or tide-producing, forces. Consider the earth and moon. The moon appears to revolve about the earth, but actually the moon and earth revolve about their common center of mass. They are held together by gravitational attraction and kept apart by an equal and opposite centrifugal force. In this earth-moon system, the tide-producing force on the earth's hemisphere nearer the moon is in the direction of the moon's attraction, or toward the moon. On the hemisphere opposite the moon the tide-producing force is in the direction of the centrifugal force, or away from the moon.

At the sublunar point, and its antipode, the moon's attractive force is vertical, in the opposite direction to gravity. Along the great circle midway between these points, the force is horizontal, parallel to the earth's surface. At any other point, the moon's tide-producing force can be resolved into horizontal and vertical components. Both are very small compared to the earth's gravity. Since the horizontal component is not operating against gravity and can draw particles of water over the surface of the earth, it is the more effective in generating tides.

The tide-producing forces, then, tend to create high tides on the sides of the earth nearest to and farthest from the moon, with a low tide belt between them. As the

earth rotates, a point on earth passes through two high and two low areas each day if the moon is over the equator (fig. 3103, A). When the moon is north or south of the equator, the force pattern is as shown in figure 3103, B, and a point on the equator passes through two equal highs, but a point in higher latitudes passes through two unequal highs or only one high. Thus, due to changes in the moon's declination, there is introduced a diurnal inequality in the pattern of the tidal forces at a particular place. There are similar forces due to the sun, and the total tide producing force is the resultant of the two. Minute tidal effects are caused by other celestial bodies.

The mathematician develops his formulas by considering the difference in attraction between a point on the earth's surface and a point at the earth's center. In accordance with Newton's law, gravitational attraction of an astronomical body varies directly as its mass and inversely as the *square* of its distance. But the tide-producing (differential) force varies directly as the mass and inversely as the *cube* of the distance. As a consequence, only the moon and sun produce any appreciable tidal effect upon the earth. Further, although the moon's mass is but a fraction of the sun's, dividing such masses by the cube of their respective distances—$(238{,}862)^3$ statute miles and $(92{,}900{,}000)^3$ statute miles, respectively—reduces the sun's tide-producing force to only 0.46 that of the moon. It is because of this that the timing of the tides is identified so closely with the motions of the moon.

Though the tide-producing forces are distributed over the earth in a regular manner, the sizes and shapes of the ocean basins and the interference of the land masses prevent the tides of the oceans from assuming a simple, regular pattern. The way in which the waters in different parts of the oceans, as well as in the smaller waterways, respond to these known regular forces is dependent in large part upon the size, depth, and configuration of the basin or waterway.

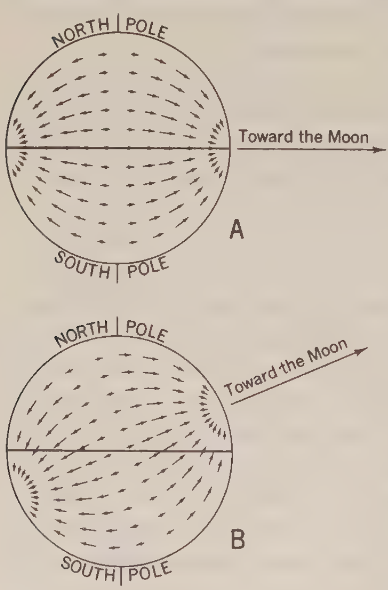

FIGURE 3103.—Tide-producing forces. The arrows represent the magnitude and direction of the horizontal component of the tide-producing force on the earth's surface. (A) When the moon is in the plane of the equator, the forces are equal in magnitude at the two points on the same parallel of latitude and 180° apart in longitude. (B) When the moon is at north (or south) declination, the forces are unequal at such points and tend to cause an inequality in the two high waters and the two low waters of a day.

Tide

3104. General features.—Tide is the periodic rise and fall of the water accompanying the tidal phenomenon. At most places it occurs twice daily. The tide rises until it reaches a maximum height, called **high tide** or **high water,** and then falls to a minimum level called **low tide** or **low water.**

The rate of rise and fall is not uniform. From low water, the tide begins to rise slowly at first but at an increasing rate until it is about halfway to high water. The rate of rise then decreases until high water is reached and the rise ceases. The falling tide behaves in a similar manner. The period at high or low water during which there is no sensible change of level is called **stand.** The difference in height between consecutive high and low waters is the **range.**

Figure 3104 is a graphical representation of the rise and fall of the tide at New York during a 24-hour period. The tide curve has the general form of a sine curve (fig. O40b).

3105. Types of tide.—A body of water has a natural period of oscillation that is dependent upon its dimensions. None of the oceans appears to be a

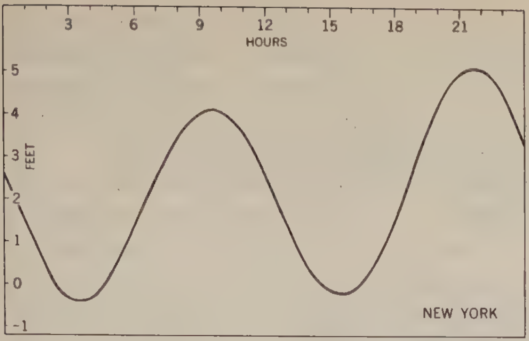

FIGURE 3104.—The rise and fall of the tide at New York, shown graphically.

single oscillating body, but rather each one is made up of a number of oscillating basins. As such basins are acted upon by the tide-producing forces, some respond more readily to daily or diurnal forces, others to semidiurnal forces, and others almost equally to both. Hence, tides at a place are classified as one of three types—**semidiurnal, diurnal,** or **mixed**—according to the characteristics of the tidal pattern occurring at the place.

In the **semidiurnal** type of tide, there are two high and two low waters each tidal day, with relatively small inequality in the high and low water heights. Tides on the Atlantic coast of the United States are representative of the semidiurnal type, which is illustrated in figure 3105a by the tide curve for Boston Harbor.

In the **diurnal** type of tide, only a single high and single low water occur each tidal day. Tides of the diurnal type occur along the northern shore of the Gulf of Mexico, in the Java Sea, the Gulf of Tonkin (off the Vietnam-China coast), and in a few other localities. The tide curve for Pakhoi, China, illustrated in figure 3105b, is an example of the diurnal type.

In the **mixed** type of tide, the diurnal and semidiurnal oscillations are both important factors and the tide is characterized by a large inequality in the high water heights, low water heights, or in both. There are usually two high and two low waters each day, but occasionally the tide may become diurnal. Such tides are prevalent along the Pacific coast of the United States and in many other parts of the world. Examples of mixed types of tide are shown in figure 3105c. At Los Angeles, it is typical that the inequalities in the high and low waters are about the same. At Seattle the greater inequalities are typically in the low waters, while at Honolulu it is the high waters that have the greater inequalities.

3106. Solar tide.—The natural period of oscillation of a body of water may accentuate either the solar or the lunar tidal oscillations. Though it is a general rule that the tides follow the moon, the relative importance of the solar effect varies in different areas. There are a few places, primarily in the South Pacific and the Indonesian areas, where the solar oscillation is the more important, and at those places the high and low waters occur at about the same time each day. At Port Adelaide, Australia (fig. 3106), the solar and lunar semidiurnal oscillations are equal and nullify one another at neaps (art. 3108).

3107. Special effects.—As a progressive wave enters shallow water, its speed is decreased. Since the trough is shallower than the crest, its retardation is greater, resulting in a steepening of the wave front. Therefore, in many rivers, the duration of rise is considerably less than the duration of fall. In a few estuaries, the advance of the low water trough is so much retarded that the crest of the

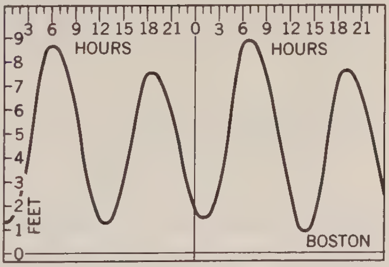

FIGURE 3105a.—Semidiurnal type of tide.

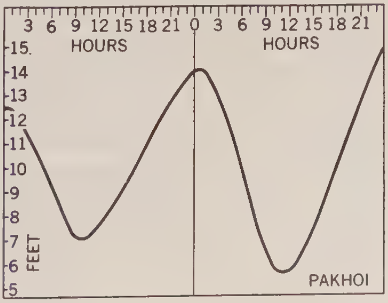

FIGURE 3105b.—Diurnal type of tide.

rising tide overtakes the low, and advances upstream as a churning, foaming wall of water called a **bore.** Bores that are large and dangerous at times of large tidal ranges may be mere ripples at those times of the month when the range is small. Examples occur in the Petitcodiac River in the Bay of Fundy and at Haining, China, in the Tsientang Kiang. The tide tables indicate where bores occur.

Other special features are the **double low water** (as at Hoek Van Holland) and the **double high water** (as at Southampton, England). At such places there is often a slight fall or rise in the middle of the high or low water period. The practical effect is to create a longer period of stand at high or low tide. The tide tables direct attention to these and other peculiarities where they occur.

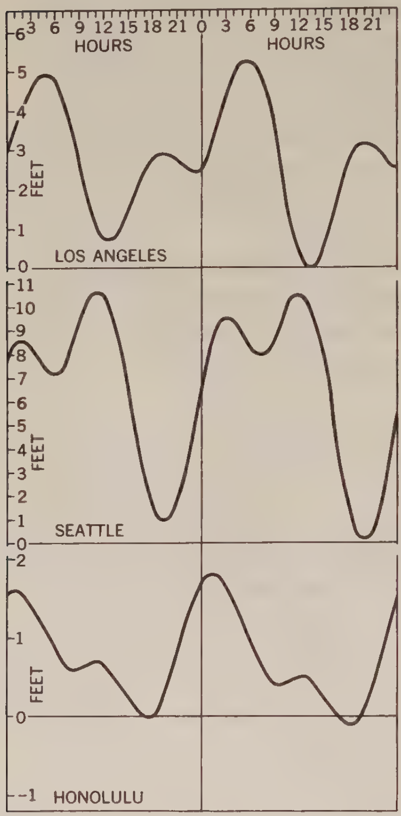

FIGURE 3105c.—Mixed types of tide.

3108. Variations in range.—Though the tide at a particular place can be classified as to type, it exhibits many variations during the month (fig. 3106). The range of the tide varies in accordance with the intensity of the tide-producing force, though there may be a lag of a day or two (**age of tide**) between a particular astronomic cause and the tidal effect.

Thus, when the moon is at the point in its orbit nearest the earth (at *perigee*), the lunar semidiurnal range is increased and **perigean** tides occur; when the moon is farthest from the earth (at *apogee*), the smaller **apogean** tides occur. When the moon and sun are in line and pulling together, as at new and full moon, **spring** tides occur (the term *spring* has nothing to do with the season of year); when the moon and sun oppose each other, as at the quadratures, the smaller **neap** tides occur.

When certain of these phenomena coincide, the great **perigean spring** tides, the small **apogean neap** tides, etc., occur.

These are variations in the semidiurnal portion of the tide. Variations in the diurnal portion occur as the moon and sun change declination. When the moon is at its maximum semi-monthly declination (either north or south), **tropic** tides occur in which the diurnal effect is at a maximum; when it crosses the equator, the diurnal effect is a minimum and **equatorial** tides occur.

It should be noted that when the range of tide is increased, as at spring tides, there is more water available only at *high* tide; at *low* tide there is less, for the high waters rise higher and the low waters fall lower at these times. There is more water at neap low water than at spring low water. With tropic tides, there is usually more depth at one low water during the day than at the other. While it is desirable to know the meanings of these terms, the best way of determining the height of the tide at any place and time is to examine the tide predictions for the place as given in the tide tables. Figure 3108 illustrates variations in the ranges and heights of tides in a locality where the water level always exceeds the charted depth.

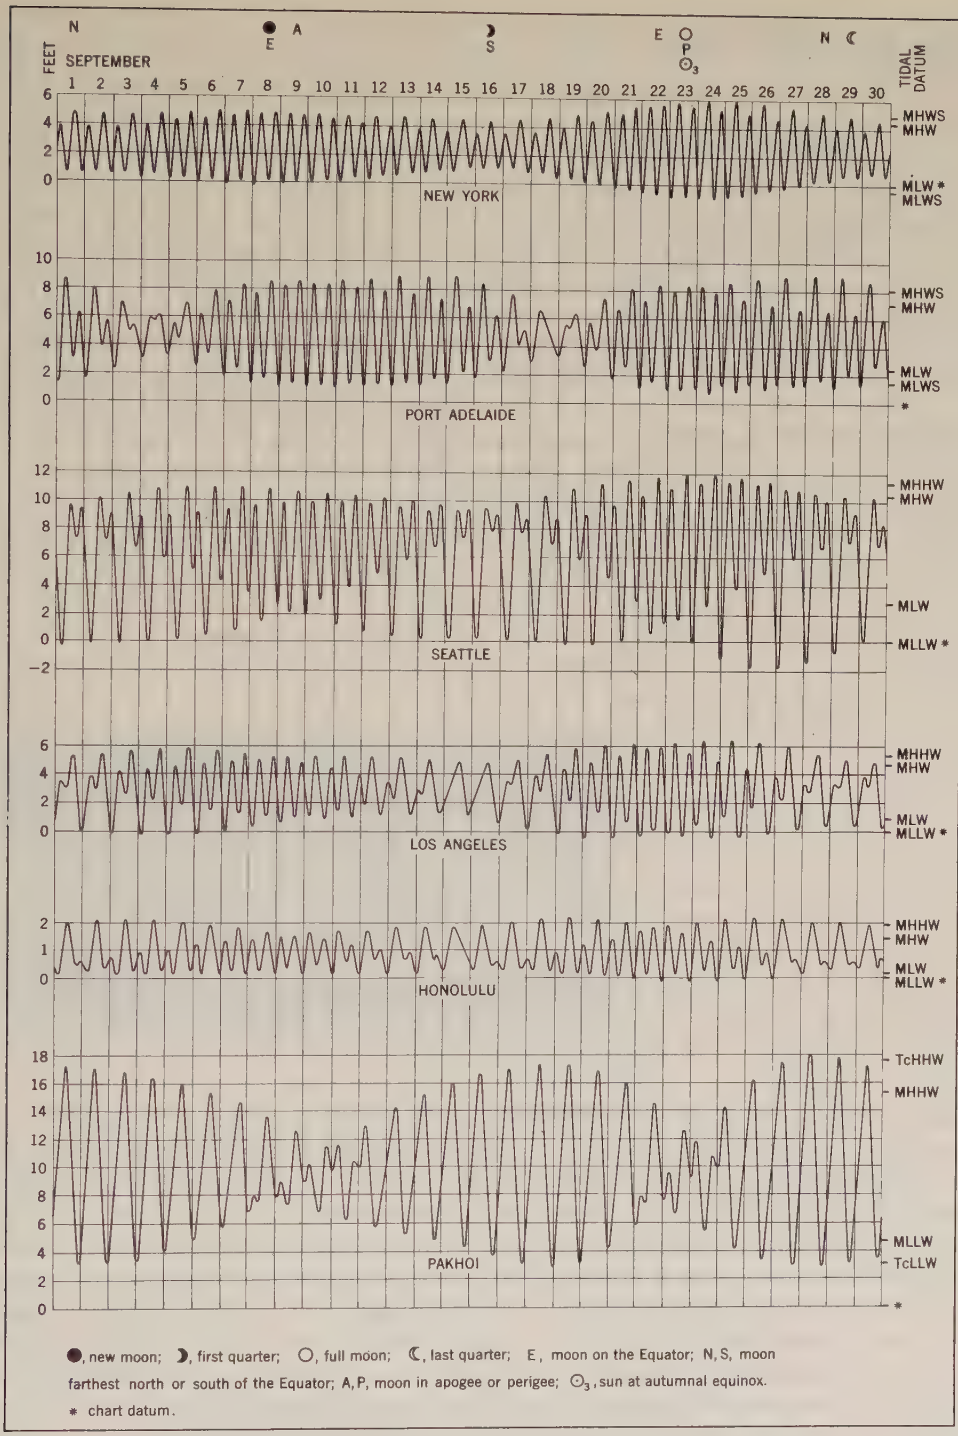

FIGURE 3106—Tidal variations at various places during a month.

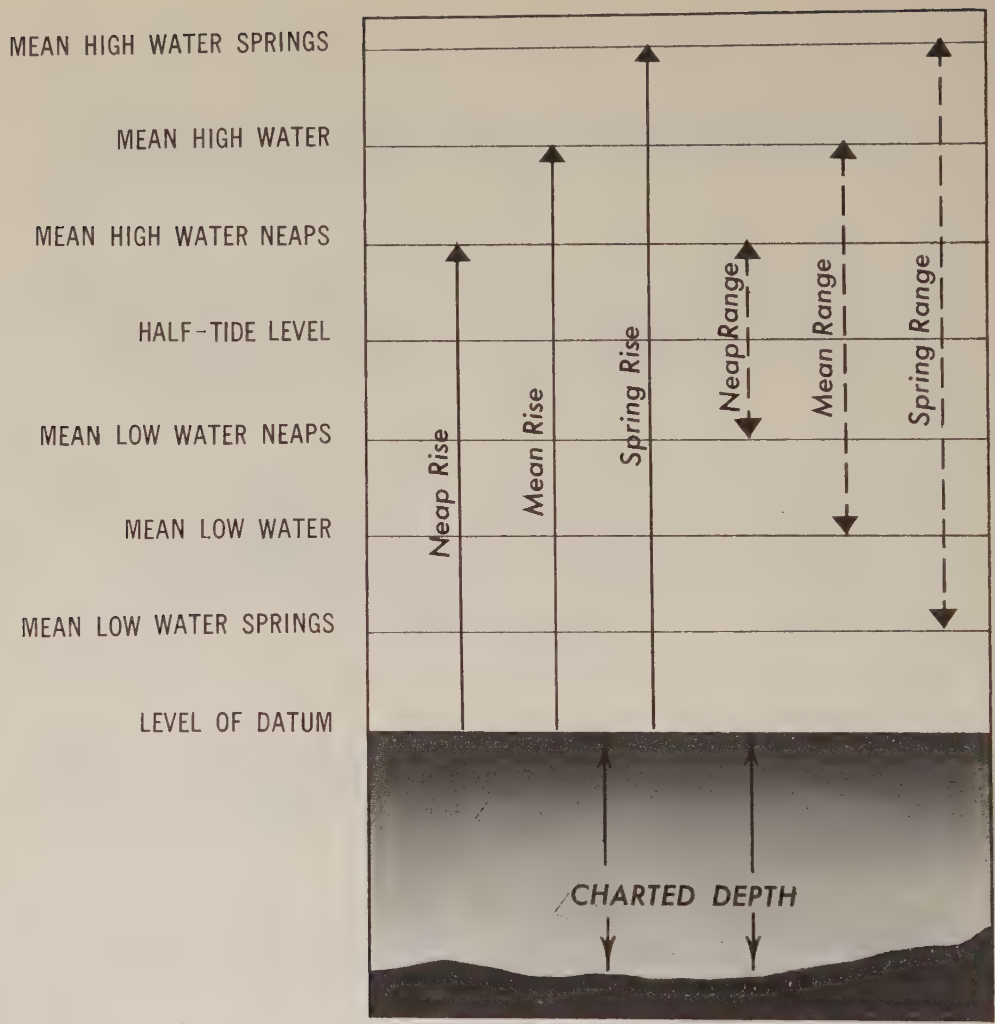

FIGURE 3108.—Variations in the ranges and heights of tide in a locality where the water level always exceeds the charted depth.

3109. Tidal cycles.—Tidal oscillations go through a number of cycles. The shortest cycle, completed in about 12 hours and 25 minutes for a semidiurnal tide, extends from any phase of the tide to the next recurrence of the same phase. During a **lunar day** (averaging 24 hours and 50 minutes) there are two highs and two lows (two of the shorter cycles) for a semidiurnal tide. The effect of the phase variation is completed in about two weeks as the moon varies from new to full or full to new. The effect of the moon's declination is also repeated about each two weeks. The cycle involving the moon's distance requires approximately a **lunar month** (a synodical month of about 29½ days). The sun's declination and distance cycles are respectively a half year and a year in length. An important lunar cycle, called the **nodal period,** is 18.6 years (usually expressed in round figures as 19 years). For a tidal value, particularly a range, to be considered a true mean, it must be either based upon observations extended over this period of time or adjusted to take account of variations known to occur during the cycle.

3110. Time of tide.—Since the lunar tide-producing force has the greater effect in producing tides at most places, the tides "follow the moon." Because of the rotation of the earth, high water lags behind meridian passage (upper and lower) of the moon. The **tidal day,** which is also the **lunar day,** is the time between consecutive transits

of the moon, or 24 hours and 50 minutes on the average. Where the tide is largely semidiurnal in type, the **lunitidal interval**—the interval between the moon's meridian transit and a particular phase of tide—is fairly constant throughout the month, varying somewhat with the tidal cycles. There are many places, however, where solar or diurnal oscillations are effective in upsetting this relationship, and the newer editions of charts of many countries now omit intervals because of the tendency to use them for prediction even though accurate predictions are available in tide tables. However, the lunitidal interval may be encountered. The interval generally given is the average elapsed time from the meridian transit (upper or lower) of the moon until the next high tide. This may may be called **mean high water lunitidal interval** or **establishment of the port.** The **high water full and change** (HWF&C) or **vulgar establishment,** sometimes given, is the average interval on days of full or new moon, and approximates the mean high water lunitidal interval.

In the ocean, the tide may be of the nature of a progressive wave with the crest moving forward, a stationary or standing wave which oscillates in a seesaw fashion, or a combination of the two. Consequently, caution should be used in inferring the time of tide at a place from tidal data for nearby places. In a river or estuary, the tide enters from the sea and is usually sent upstream as a progressive wave, so that the tide occurs progressively later at various places upstream.

3111. Tidal datums.—A **tidal datum** is a level from which heights and depths are measured. There are a number of such levels of reference that are important to the mariner. The relation of the tide each day during a month to these datums is shown, for certain places, in figure 3106.

The most important level of reference to the mariner is the datum of soundings on charts. Since the tide rises and falls continually while soundings are being taken during a hydrographic survey, the tide should be observed during the survey so that soundings taken at all stages of the tide can be reduced to a common datum. Soundings on charts show depths below a selected low water datum (occasionally mean sea level), and tide predictions in tide tables show heights above the same level. The depth of water available at any time is obtained by adding the height of the tide at the time in question to the charted depth, or by subtracting the predicted height if it is negative.

By international agreement, the level used as chart datum should be just low enough so that low waters do not go far below it. At most places, however, the level used is one determined from a mean of a number of low waters (usually over a 19-year period); therefore some low waters can be expected to fall below it. The following are some of the datums in general use.

The highest low water datum in considerable use is **mean low water (MLW),** which is the average height of all low waters at a place. About half of the low waters fall below it. **Mean low water springs** (MLWS), usually shortened to **low water springs,** is the average level of the low waters that occur at the times of spring tides. **Mean lower low water** (MLLW) is the average height of the lower low waters at a place. **Tropic lower low water** (TcLLW) is the average height of the lower low waters (or of the single daily low waters if the tide becomes diurnal) that occur when the moon is near maximum declination and the diurnal effect is most pronounced. This datum is not in common use as a tidal reference. **Indian spring low water** (ISLW) sometimes called **Indian tide plane** or **harmonic tide plane,** is a low datum that includes the spring effect of the semi-diurnal portion of the tide and the tropic effect of the diurnal portion. It is about the level of lower low water of mixed tides at the time that the moon's maximum declination coincides with the time of new or full moon. **Mean lower low water springs** is the aver-

age level of the lower of the two low waters on the days of spring tides. Some still lower datums used on charts are determined from tide observations and some are determined arbitrarily and later referred to the tide. Most of them fall close to one or the other of the following two datums. **Lowest normal low water** is a datum that approximates the average height of monthly lowest low waters, discarding any tides disturbed by storms. **Lowest low water** is an extremely low datum. It conforms generally to the lowest tide observed, or even somewhat lower. Once a tidal datum is established, it is generally retained for an indefinite period, even though it might differ slightly from a better determination from later observations. When this occurs, the established datum may be called **low water datum, lower low water datum,** etc.

In some areas where there is little or no tide, such as the Baltic Sea, **mean sea level** (MSL) is used as chart datum. This is the average height of the surface of the sea for all stages of the tide over a 19-year period. This may differ slightly from **half-tide level,** which is the level midway between mean high water and mean low water.

Inconsistencies of terminology are found among charts of different countries and between charts issued at different times. For example, the spring effect as defined here is a feature of only the semidiurnal tide, yet it is sometimes used synonymously with tropic effect to refer to times of increased range of a diurnal tide. Such inconsistencies are being reduced through increased international cooperation.

Large-scale charts usually specify the datum of soundings and may contain a tide note giving mean heights of the tide at one or more places on the chart. These heights are intended merely as a rough guide to the change in depth to be expected under the specified conditions. They should not be used for the prediction of heights on any particular day. Such predictions should be obtained from *tide tables* (arts. 921–924). The tidal datums used in various areas are listed in appendix M.

3112. High water datums.—Heights of land features are usually referred on nautical charts to a high water datum. The one used on charts of the United States, its territories, and possessions, and widely used elsewhere, is **mean high water (MHW),** which is the average height of all high waters over a 19-year period. Any other high water datum in use on charts is likely to be higher than this. Other high water datums are **mean high water springs (MHWS),** which is the average level of the high waters that occur at the time of spring tides; **mean higher high water (MHHW),** which is the average height of the higher high waters of each day; and **tropic higher high water (TcHHW),** which is the average height of the higher high waters (or the single daily high waters if the tide becomes diurnal) that occur when the moon is near maximum declination and the diurnal effect is most pronounced. A reference merely to "high water" leaves some doubt as to the specific level referred to, for the height of high water varies from day to day. Where the range is large, the variation during a two-week period may be considerable.

3113. Observations and predictions.—Since the tide at different places responds differently to the tide-producing forces, the nature of the tide at any place can be determined most accurately by actual observation. The predictions in tide tables and the tidal data on nautical charts are based upon such observations.

Tides are usually observed by means of a continuously recording gage. A year of observations is the minimum length desirable for determining the **harmonic constants** used in prediction. For establishing mean sea level and the long-time changes in the relative elevations of land and sea, as well as for other special uses, observations have been made over periods of 20, 30, and even 50 years at important locations. Observations for a month or less will establish the *type* of tide and suffice for comparison with a longer series of a similar type to determine tidal differences and constants.

Mathematically, the variations in the lunar and solar tide-producing forces, such as those due to changing phase, distance, and declination, are considered as separate constituent forces, and the **harmonic analysis** of observations reveals the response of each constituent of the tide to its corresponding force. At any one place this response remains constant and is shown for each constituent by **harmonic constants** which are in the form of a phase angle for the time relation and an amplitude for the height. Harmonic constants are used in making technical studies of the tide and predictions on the **tide predicting machine.** Most published tide predictions are made by machine.

3114. Tide tables are published annually by most of the maritime nations of the world. They consist primarily of two parts. One contains predictions of the time and height of each high and low water for every day of the year for many important ports called **reference stations.** The other part contains tidal differences for thousands of other places, called **subordinate stations,** and specifies the reference station to which the differences are to be applied in order to obtain time and height of tide for any day at the subordinate station. The type of tide at a subordinate station is the same as at its reference station. The use of tide tables is explained in articles 921–924.

3115. Meteorological effects.—The foregoing discussion of tide behavior assumes normal weather conditions. The level of the sea is affected by wind and atmospheric pressure. In general, onshore winds raise the level and offshore winds lower it, but the amount of change varies at different places. During periods of low atmospheric pressure, the water level tends to be higher than normal. For a stationary low, the increase in elevation can be found by the formula

$$R_0=0.0325\ (1010-P),$$

in which R_0 is the increase in elevation in feet, and P is the atmospheric pressure in millibars. This is equal approximately to one centimeter per millibar depression, or one foot (13.6 inches) per inch depression. For a moving low, the increase in elevation is given by the formula

$$R=\frac{R_0}{1-\frac{C^2}{gh}},$$

in which R is the increase in elevation in feet, R_0 is the increase in feet for a stationary low, C is the rate of motion of the low in feet per second, g is the acceleration due to gravity (32.2 feet per second per second), and h is the depth of water in feet.

Where the range of tide is very small, the meteorological effect may sometimes be greater than the normal tide.

Tidal Current

3116. Tidal and nontidal currents.—Horizontal movement of the water is **current.** It may be classified as "tidal" and "nontidal." **Tidal current** is the periodic horizontal flow of water accompanying the rise and fall of the tide, and results from the same cause. **Nontidal current** is any current not due to the tidal movement. Nontidal currents include the permanent currents in the general circulatory system of the oceans as well as temporary currents arising from meteorological conditions. The current experienced at any time is usually a combination of tidal and nontidal currents.

In navigation, the effect of the tidal current is often of more importance than the changing depth due to the tide, and many mariners speak of "the tide," when they have in mind the flow of the tidal current.

3117. General features.—Offshore, where the direction of flow is not restricted by any barriers, the tidal current is **rotary;** that is, it flows continuously, with the direction changing through all points of the compass during the tidal period. The tendency

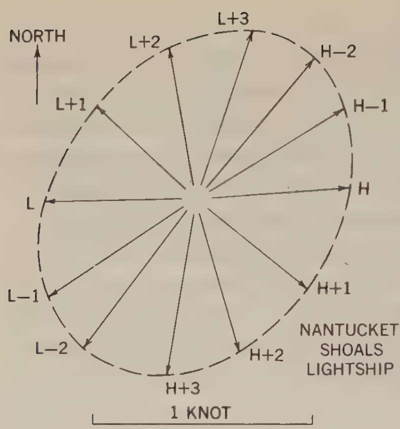

FIGURE 3117a.—Rotary tidal current. Times are hours before and after high and low tide at Nantucket Shoals Lightship. The bearing and length of each arrow represents the hourly direction and speed of the current. See figure 3120a.

for the rotation in direction has its origin in the deflecting force of the earth's rotation, and unless modified by local conditions, the change is clockwise in the northern hemisphere and counterclockwise in the southern hemisphere. The speed usually varies throughout the tidal cycle, passing through two maximums in approximately opposite directions, and two minimums about halfway between the maximums in time and direction. Rotary currents can be depicted as in figure 3117a, by a series of arrows representing the direction and speed of the current at each hour. This is sometimes called a **current rose.** Because of the elliptical pattern formed by the ends of the arrows, it is also referred to as a **current ellipse.**

In rivers or straits, or where the direction of flow is more or less restricted to certain channels, the tidal current is **reversing;** that is, it flows alternately in approximately opposite directions with an instant or short period of little or no current, called **slack water,** at each reversal of the current. During the flow in each direction, the speed varies from zero at the time of slack water to a maximum, called **strength of flood** or **ebb,** about midway between the slacks. Reversing currents can be indicated graphically, as in figure 3117b, by arrows that represent the speed of the current at each hour. The flood is usually depicted above the slack water line and the ebb below it. The tidal current curve formed by the ends of the arrows has the same characteristic sine form as the tide curve. (In illustrations for certain purposes, as in figures 3118b and 3120b, it is convenient to omit the arrows and show only the curve.)

A slight departure from the sine form is exhibited by the reversing current in a strait, such as East River, New York, that connects two tidal bodies of water. The tides at the two ends of a strait are seldom in phase or equal in range, and the current, called **hydraulic current,** is generated largely by the continuously changing difference in height of water at the two ends. The speed of a hydraulic current varies nearly as the square root of the difference in height. The speed reaches a maximum more quickly and remains at strength for a longer period than shown in figure 3117b, and the period of weak current near the time of slack is considerably shortened.

The current *direction* or **set** is the direction *toward* which the current flows. The *speed* is sometimes called the **drift.** The term "velocity" is often used as the equivalent of "speed" when referring to current, although strictly "velocity" implies direction as well as speed. The term "strength" is also used to refer to speed, but more often to greatest speed between consecutive slack waters. The movement toward shore or upstream is the **flood,** the movement away from shore or downstream is the **ebb.** In a purely semidiurnal type of current unaffected by nontidal flow, the flood and ebb each last about six hours and 13 minutes. But if there is either diurnal inequality or nontidal flow, the durations of flood and ebb may be quite unequal.

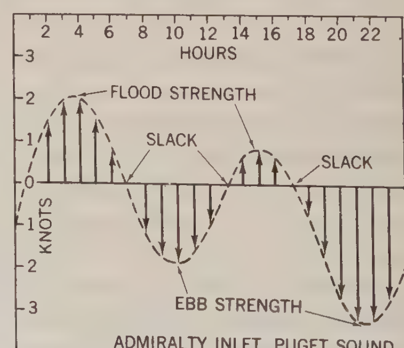

FIGURE 3117b.—Reversing tidal current. (Such graphs may show only the curved pattern without the arrows, as in figures 3118b and 3120b.) See figure 3120b.

3118. Types of tidal current.—Tidal currents may be of the **semidiurnal, diurnal,** or **mixed** type; corresponding to a considerable degree to the type of tide at the place, but often with a stronger semidiurnal tendency.

The tidal currents in tidal estuaries along the Atlantic coast of the United States are examples of the semidiurnal type of reversing current. At Mobile Bay entrance they are almost purely diurnal. At most places, however, the type is mixed to a greater or lesser degree. At Tampa and Galveston entrances there is only one flood and one ebb each day when the moon is near its maximum declination, and two floods and two ebbs each day when the moon is near the equator. Along the Pacific coast of the United States there are generally two floods and two ebbs every day, but one of the floods or ebbs has a greater speed and longer duration than the other, the inequality varying with the declination of the moon. The inequalities in the current often differ considerably from place to place even within limited areas, such as adjacent passages in Puget Sound and various passages between the Aleutian Islands. Figure 3118a shows several types of reversing current. Figure 3118b shows how the flood disappears as the diurnal inequality increases at one station.

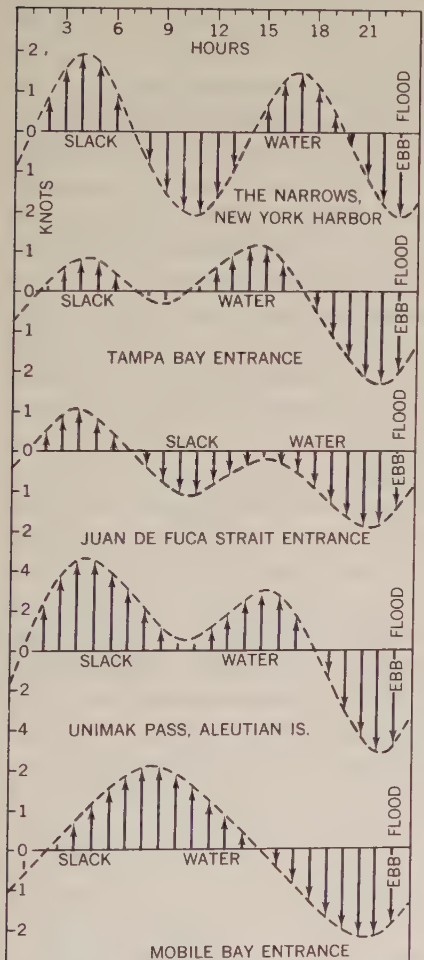

FIGURE 3118a.—Several types of reversing current. The pattern changes gradually from day to day, particularly for mixed types, passing through cycles somewhat similar to that shown for tides in figure 3106.

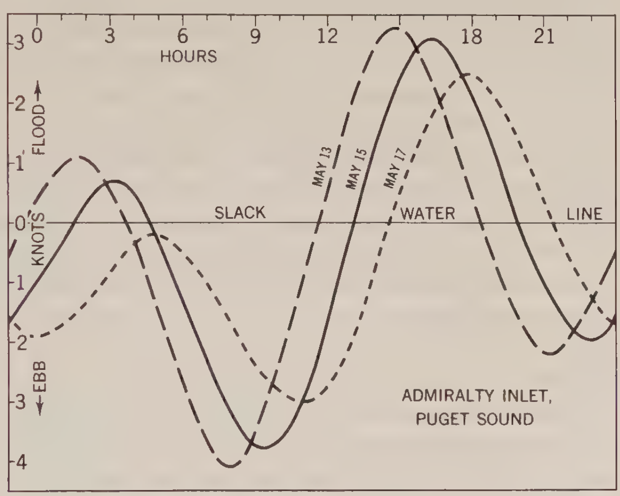

FIGURE 3118b.—Changes in a current of the mixed type. Note that each day as the inequality increases, the morning slacks draw together in time until on the 17th the morning flood disappears. On that day the current ebbs throughout the morning.

Offshore rotary currents that are purely semidiurnal repeat the elliptical pattern (fig. 3117a) each tidal cycle of 12 hours and 25 minutes. If there is considerable diurnal inequality, the plotted hourly current arrows describe a set of two ellipses of different sizes during a period of 24 hours and 50 minutes, as shown in figure 3118c, and the greater the diurnal inequality, the greater the difference between the sizes of the two ellipses. In a completely diurnal rotary current, the smaller ellipse disappears and only one ellipse is produced in 24 hours and 50 minutes.

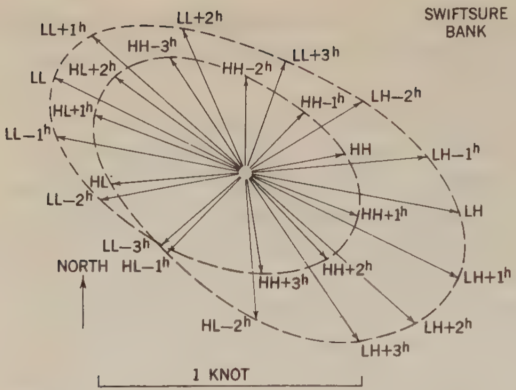

FIGURE 3118c.—Rotary tidal current with diurnal inequality. Times are in hours referred to tides (higher high, lower low, lower high, and higher low) at Swiftsure Bank.

3119. Variations and cycles.—Tidal currents have periods and cycles similar to those of the tides (art. 3109), and are subject to similar variations, but flood and ebb of the current do not necessarily occur at the same times as the rise and fall of the tide. The relationship is explained further in article 3121.

The speed at strength increases and decreases during the two-week period, month, and year with the variations in the range of tide. Thus, the stronger **spring** and **perigean currents** occur near the times of new and full moon and near the times of the moon's perigee, or at times of spring and perigean tides (art. 3108); the weaker **neap** and **apogean currents** occur at the times of neap and apogean tides; **tropic currents** with increased diurnal speeds or with larger diurnal inequalities in speed occur at times of tropic tides; and **equatorial currents** with a minimum diurnal effect occur at times of equatorial tides; etc.

As with the tide, a *mean value* represents an average obtained from a 19-year series. Since a series of current observations is usually limited to a day or two, and seldom covers more than a month or two, it is necessary to adjust the observed values, usually by comparison with tides at a nearby place, to obtain such a mean.

3120. Effect of nontidal flow.—The current existing at any time is seldom purely tidal, but usually includes also a nontidal current that is due to drainage, oceanic circulation, wind, or other cause. The method in which tidal and nontidal currents combine is best explained graphically, as in figures 3120a and 3120b. The pattern of the tidal current remains unchanged, but the curve is shifted from the point or line from which the currents are measured in the direction of the nontidal current and by an amount equal to it. It is sometimes more convenient graphically merely to move the line or point of origin in the opposite direction.

Thus, the speed of the current flowing in the direction of the nontidal current is increased by an amount equal to the magnitude of the nontidal current, and the speed of the current flowing in the opposite direction is decreased by an equal amount. In figure 3120a a nontidal current is represented both in direction and speed by the vector AO. Since this is greater than the speed of the tidal current in the opposite direction, the point A is outside the ellipse. The direction and speed of the combined tidal and nontidal currents at any time is represented by a vector from A to that point on the curve representing the given time, and can be scaled from the graph. The strongest and weakest currents may no longer be in the directions of the maximum and minimum of the tidal current. In a reversing current (fig. 3120b), the effect is to advance the time of one slack and to retard the following one. If the speed of

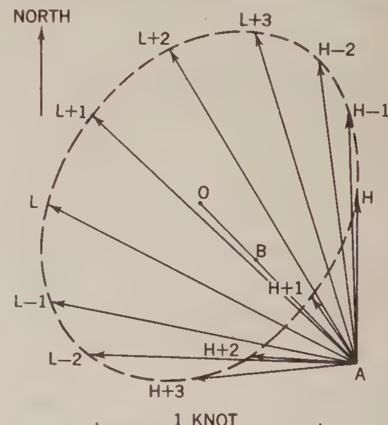

FIGURE 3120a.—Effect of nontidal current on the rotary tidal current of figure 3117a. If the nontidal current is northwest at 0.3 knot, it may be represented by BO, and all hourly directions and speeds will then be measured from B. If it is 1.0 knot, it will be represented by AO and the actual resultant hourly directions and speeds will be measured from A, as shown by the arrows.

the nontidal current exceeds that of the reversing tidal current, the resultant current flows continuously in one direction without coming to a slack. In this case, the speed varies from a maximum to a minimum and back to a maximum in each tidal cycle. In figure 3120b the horizontal line *A* represents slack water if only tidal currents are present. Line *B* represents the effect of a 0.5-knot nontidal ebb, and line *C* the effect of a 1.0-knot nontidal ebb. With the condition shown at *C* there is only one flood each tidal day. If the nontidal ebb were to increase to approximately two knots, there would be no flood, two maximum ebbs and two minimum ebbs occurring during a tidal day.

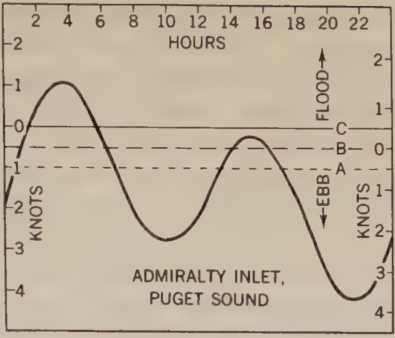

FIGURE 3120b.—Effect of nontidal current on the reversing tidal current of figure 3117b. If the nontidal current is 0.5 knot in the ebb direction, the ebb is increased by moving the slack water line from position *A* up 0.5 knot to position *B*. Speeds will then be measured from this broken line as shown by the scale on the right, and times of slack are changed. If the nontidal current is 1.0 knot in the ebb direction, as shown by line *C*, the speeds are as shown on the left, and the current will not reverse to a flood in the afternoon; it will merely slacken at about 1500.

3121. Relation between time of tidal current and time of tide.—At many places where current and tide are both semidiurnal, there is a definite relation between times of current and times of high and low water in the locality. Current atlases and notes on nautical charts often make use of this relationship by presenting for particular locations the direction and speed of the current at each succeeding hour after high and low water at a place for which tide predictions are available.

In localities where there is considerable diurnal inequality in tide or current, or where the type of current differs from the type of tide, the relationship is not constant, and it may be hazardous to try to predict the times of current from times of tide. Note the current curve for Unimak Pass in the Aleutians in figure 3118a. It shows the current as predicted in the tidal current tables. Predictions of high and low waters in the tide tables might have led one to expect the current to change from flood to ebb in the late morning, whereas actually the current continued to run flood with some strength at that time.

Since the relationship between times of tidal current and tide is not everywhere the same, and may be variable at the same place, one should exercise extreme caution in using general rules. The belief that slacks occur at local high and low tides and that the maximum flood and ebb occur when the tide is rising or falling most rapidly may be approximately true at the seaward entrance to, and in the upper reaches of, an inland tidal waterway. But generally this is not true in other parts of inland waterways. When an inland waterway is extensive or its entrance constricted, the slacks in some parts of the waterway often occur midway between the times of high and low tide. Usually in such waterways the relationship changes from place to place as one progresses upstream, slack water getting progressively later with respect to the local tide until at the head of tidewater (the inland limit of water affected by a tide) the slacks occur at the times of high and low tide.

3122. Relation between speed of current and range of tide.—The variation in the speed of the tidal current from place to place is not necessarily consistent with the range of tide. It may be the reverse. For example, currents are weak in the Gulf of Maine where the tides are large, and strong near Nantucket Island and in Nantucket Sound where the tides are small.

At any one place, however, the speed of the current at strength of flood and ebb varies during the month in about the same proportion as the range of tide, and

one can use this relationship to determine the relative strength of currents on any day.

3123. Variation across an estuary.—In inland tidal waterways the *time* of tidal current varies across the channel from shore to shore. On the average, the current turns earlier near shore than in midstream, where the speed is greater. Differences of half an hour to an hour are not uncommon, but the difference varies and the relationship may be nullified by the effect of nontidal flow.

The *speed* of the current also varies across the channel, usually being greater in midstream or midchannel than near shore, but in a winding river or channel the strongest currents occur near the concave shore. Near the opposite (convex) shore the currents are weak or may eddy.

3124. Variation with depth.—In tidal rivers the subsurface current acting on the lower portion of the hull may differ considerably from the surface current. An appreciable subsurface current may be present when the surface movement appears to be practically slack, and the subsurface current may even be flowing with appreciable speed in the opposite direction to the surface current.

In a tidal estuary, particularly in the lower reaches where there is considerable difference in density from top to bottom, flood usually begins earlier near the bottom than at the surface. The differences may be an hour or two or as little as a few minutes, depending upon the estuary, the location in the estuary, and freshet conditions. Even when the fresh water runoff becomes so great as to prevent the surface current from flooding, it may still flood below the surface. The difference in time of ebb from surface to bottom is normally small but subject to variation with time and location.

The ebb speed at strength usually decreases gradually from top to bottom, but the speed of flood at strength often is stronger at subsurface depths than at the surface.

3125. Observations.—Observations of the current are made by means of a current meter or current pole and log line. In the past, most successful meters required a vessel and observers in continual attendance, as is necessary with the pole and line. Because of the difficulty and expense of such observations, they usually covered only a period of a day or two at a place. Observations of a month are the exception, and longer series were obtained only where ship and observers were available because of other duties, such as at lightships, where observations have been continued over a number of years.

Newer meters have been and are being developed that are suspended from a buoy and that record either in the buoy or send speed and direction impulses by radio to a base station on ship or land. With them, the period of observation has been increased so that in some recent surveys of United States harbors, the minimum period of observation was four days, with observations at several stations being continued over a period of 15 to 29 days.

3126. Tidal current tables and other sources of information.—The navigator should not attempt to predict currents without specific information for the locality in which he is interested. Such information is contained in various forms in many navigational publications.

Tidal current tables, issued annually, list daily predictions of the times and strengths of flood and ebb currents, and of the times of intervening slacks. Due to lack of observational data, coverage is considerably more limited than for the tides. The tidal current tables do include supplemental data by which tidal current predictions can be determined for many places in addition to those for which daily predictions are given. The predictions are made by the tide-predicting machine, using current harmonic constants that are obtained by analyzing current observations in the same manner as for tides (art. 3113). The use of tidal current tables is explained in articles 925–929.

Sailing directions and **coast pilots** issued by maritime nations include general descriptions of current behavior in various localities throughout the world.

Tidal current charts. A number of important harbors and waterways are covered by sets of tidal current charts showing graphically the hourly current movement.

CHAPTER XXXII

OCEAN CURRENTS

3201. Introduction.—The movement of water comprising the oceans is one of the principal sources of discrepancy between dead reckoning and actual positions of vessels. Water in essentially horizontal motion is called a **current,** the direction *toward* which it moves being the **set,** and its speed the **drift.** A well-defined current extending over a considerable region of the ocean is called an **ocean current.**

A **periodic current** is one the speed or direction of which changes cyclically at somewhat regular intervals, as a tidal current. A **seasonal current** is one which has large changes in speed or direction due to seasonal winds. A **permanent current** is one which experiences relatively little periodic or seasonal change.

A **coastal current** flows roughly parallel to a coast, outside the surf zone, while a **longshore current** is one parallel to a shore, inside the surf zone, and generated by waves striking the beach at an angle. Any current some distance from the shore may be called an **offshore current,** and one close to the shore an **inshore current.**

A **surface current** is one present at the surface, particularly one that does not extend more than a relatively few feet below the surface. A **subsurface current** is one which is present below the surface only.

There is evidence to indicate that the strongest ocean currents consist of relatively narrow, high-speed streams that follow winding, shifting courses. Often associated with these currents are secondary **countercurrents** flowing adjacent to them but in the opposite direction, and somewhat local, roughly circular, **eddy currents.** A relatively narrow, deep, fast-moving current is sometimes called a **stream current,** and a broad, shallow, slow-moving one a **drift current.**

3202. Causes of ocean currents.—Although man's knowledge of the processes which produce and maintain ocean currents is far from complete, he does have a general understanding of the principal factors involved. The primary generating force is wind, and the chief secondary force is the density differences in the water. In addition, such factors as depth of water, underwater topography, shape of the basin in which the current is running, extent and location of land, and deflection by the rotation of the earth all affect the oceanic circulation.

3203. Wind currents.—The stress of wind blowing across the sea causes the surface layer of water to move. This motion is transmitted to each succeeding layer below the surface, but due to internal friction within the water, the rate of motion decreases with depth. The current thus set up is called a **wind current.** Although there are many variables, it is generally true that a steady wind for about 12 hours is needed to establish such a current.

A wind current does not flow in the direction of the wind, being deflected by Coriolis force (art. 1611), due to rotation of the earth. This deflection is toward the *right* in the northern hemisphere, and toward the *left* in the southern hemisphere. The Coriolis force is greater in higher latitudes, and is more effective in deep water. In general, the difference between wind direction and surface wind-current direction varies from about 15° along shallow coastal areas to a maximum of 45° in the deep oceans. The angle increases with depth. At several hundred fathoms the current may flow in the opposite direction to the surface current.

The speed of the current depends upon the speed of the wind, its constancy, the length of time it has blown, and other factors. In general, however, about two percent of the wind speed, or a little less, is a good average for deep water where the wind has been blowing steadily for at least 12 hours.

3204. Currents related to density differences.—As indicated in article 3009, the density of water varies with salinity, temperature, and pressure. At any given depth, the differences in density are due to differences in temperature and salinity. When suitable information is available, a map showing geographical density distribution at a certain depth could be drawn, with lines connecting points of equal density. These **isopycnic lines,** or lines connecting points at which a given density occurs at the same depth, would be similar to isobars on a weather map (art. 3827), and would serve an analogous purpose, showing areas of high density and those of low density. In an area of high density, the water surface is lower than in an area of low density, the maximum difference in height being of the order of one to two feet in 40 miles. Because of this difference, water tends to flow from an area of higher water (low density) to one of lower water (high density), but due to rotation of the earth, it is deflected toward the right in the northern hemisphere, and toward the left in the southern hemisphere. Thus, a circulation is set up similar to the cyclonic and anticyclonic circulation in the atmosphere. The greater the density gradient (rate of change with distance), the faster the related current.

3205. Oceanic circulation.—A number of ocean currents flow with great persistence, setting up a circulation that continues with relatively little change throughout the year. Because of the influence of wind in creating current (art. 3203), there is a relationship between this oceanic circulation and the general circulation of the atmosphere (art. 3804). The oceanic circulation is shown in figure 3205, with the names of the major ocean currents. Some differences in opinion exist regarding the names and limits of some of the currents, but those shown are representative. The spacing of the lines is a general indication of speed, but conditions vary somewhat with the season. This is particularly noticeable in the Indian Ocean and along the South China coast, where currents are influenced to a marked degree by the monsoons (art. 3810).

3206. Atlantic Ocean currents.—The trade winds (art. 3806), which blow with great persistence, set up a system of **equatorial currents** which at times extends over as much as 50° of latitude, or even more. There are two westerly flowing currents conforming generally with the areas of trade winds, separated by a weaker, easterly flowing countercurrent.

The **north equatorial current** originates to the northward of the Cape Verde Islands and flows almost due west at an average speed of about 0.7 knot.

The **south equatorial current** is more extensive. It starts off the west coast of Africa, south of the Gulf of Guinea, and flows in a generally westerly direction at an average speed of about 0.6 knot. However, the speed gradually increases until it may reach a value of 2.5 knots or more off the east coast of South America. As the current approaches Cabo de São Roque, the eastern extremity of South America, it divides, the southern part curving toward the south along the coast of Brazil, and the northern part being deflected by the continent of South America toward the north.

Between the north and south equatorial currents a weaker **equatorial countercurrent** sets toward the east in the general vicinity of the doldrums (art. 3805). This is fed by water from the two westerly flowing equatorial currents, particularly the south equatorial current. The extent and strength of the equatorial countercurrent changes with the seasonal variations of the wind. It reaches a maximum during July and August, when it extends from about 50° west longitude to the Gulf of Guinea.

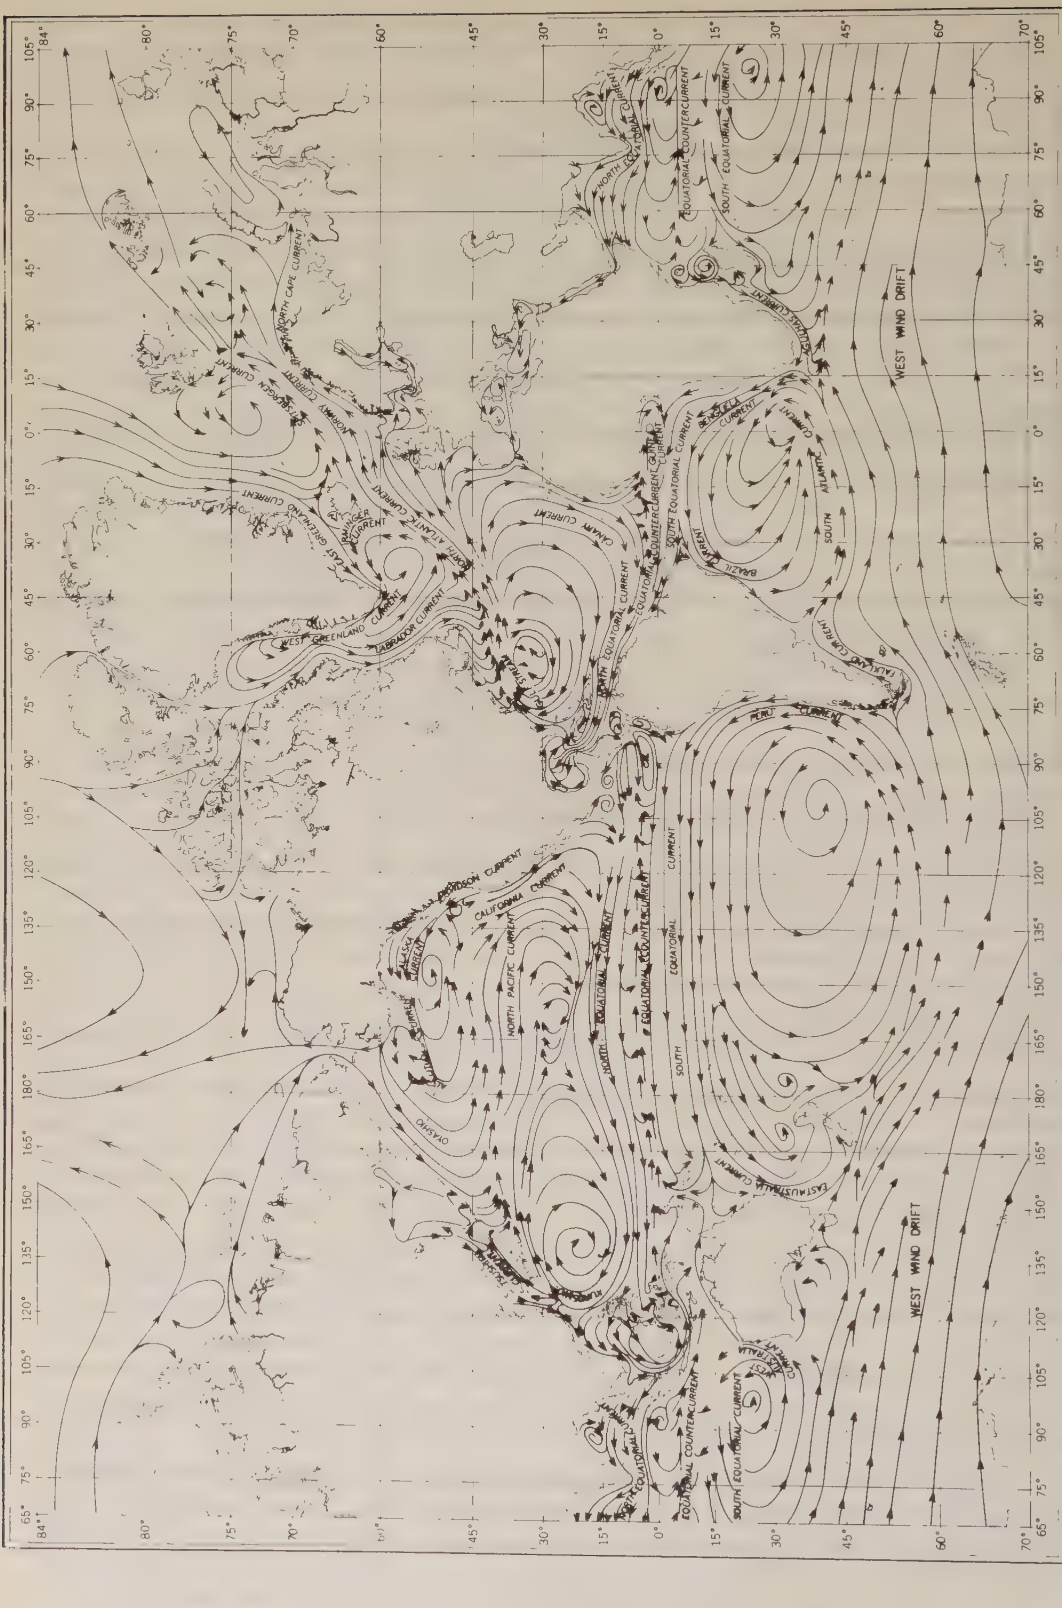

FIGURE 3205.—Major surface currents of the world (northern hemisphere winter).

During its minimum, in December and January, it is of very limited extent, the western portion disappearing altogether.

That part of the south equatorial current flowing along the northern coast of South America which does not feed the equatorial countercurrent unites with the north equatorial current at a point west of the equatorial countercurrent. A large part of the combined current flows through various passages between the Windward Islands, into the Caribbean Sea. It sets toward the west, and then somewhat north of west, finally arriving off the Yucatan peninsula. From here, some of the water curves toward the right, flowing some distance off the shore of the Gulf of Mexico, and part of it curves more sharply toward the east and flows directly toward the north coast of Cuba. These two parts reunite in the Straits of Florida to form the most remarkable of all ocean currents, the **Gulf Stream.** Off the southeast coast of Florida this current is augmented by a current flowing along the northern coasts of Puerto Rico, Hispaniola, and Cuba. Another current flowing eastward of the Bahamas joins the stream north of these islands.

The Gulf Stream follows generally along the east coast of North America, flowing around Florida, northward and then northeastward toward Cape Hatteras, and then curving toward the east and becoming broader and slower. After passing the Grand Banks, it turns more toward the north and becomes a broad drift current flowing across the North Atlantic. That part in the Straits of Florida is sometimes called the **Florida current.**

A tremendous volume of water flows northward in the Gulf Stream. It can be distinguished by its deep indigo-blue color, which contrasts sharply with the dull green of the surrounding water. It is accompanied by frequent squalls. When the Gulf Stream encounters the cold water of the Labrador current, principally in the vicinity of the Grand Banks, there is little mixing of the waters. Instead, the junction is marked by a sharp change in temperature. The line or surface along which this occurs is called the **cold wall.** When the warm Gulf Stream water encounters cold air, evaporation is so rapid that the rising vapor may be visible as frost smoke (art. 3815). The stream carries large quantities of gulfweed from the tropics to higher latitudes.

Recent investigations have shown that the current itself is much narrower and faster than previously supposed, and considerably more variable in its position and speed. The maximum current off Florida ranges from about two to four knots. To the northward the speed is generally less, and decreases further after the current passes Cape Hatteras. As the stream meanders and shifts position, eddies sometimes break off and continue as separate, circular flows until they dissipate. Boats in the Bermuda Race have been known to be within sight of each other and be carried in opposite directions by different parts of the same current. As the current shifts position, its extent does not always coincide with the area of warm, blue water. When the sea is relatively smooth, the edges of the current are marked by ripples.

Information is not yet available to permit prediction of the position and speed of the current at any future time, but it has been found that tidal forces apparently influence the current, which reaches its daily maximum speed about three hours after transit of the moon. The current generally is faster at the time of neap tides than at spring tides. When the moon is over the equator, the stream is narrower and faster than at maximum northerly or southerly declination. Variations in the trade winds (art. 3806) also affect the current.

As the Gulf Stream continues eastward and northeastward beyond the Grand Banks, it gradually widens and decreases speed until it becomes a vast, slow-moving drift current known as the **North Atlantic current,** in the general vicinity of the pre-

vailing westerlies (art. 3808). In the eastern part of the Atlantic it divides into the **northeast drift current** and the **southeast drift current.**

The northeast drift current continues in a generally northeasterly direction toward the Norwegian Sea. As it does so, it continues to widen and decrease speed. South of Iceland it branches to form the **Irminger current** and the **Norway current.** The Irminger current curves toward the north and northwest to join the East Greenland current southwest of Iceland. The Norway current continues in a northeasterly direction along the coast of Norway. Part of it, the **North Cape current,** rounds North Cape into the Barents Sea. The other part curves toward the north and becomes known as the **Spitzbergen current.** Before reaching Svalbard (Spitzbergen), it curves toward the west and joins the cold **east Greenland current** flowing southward in the Greenland Sea. As this current flows past Iceland, it is further augmented by the Irminger current.

Off Kap Farvel, at the southern tip of Greenland, the east Greenland current curves sharply to the northwest, following the coast line. As it does so, it becomes known as the **west Greenland current.** This current continues along the west coast of Greenland, through Davis Strait, and into Baffin Bay. Both east and west Greenland currents are sometimes known by the single name **Greenland current.**

In Baffin Bay the Greenland current follows generally the coast, curving westward off Kap York to form the southerly flowing **Labrador current.** This cold current flows southward off the coast of Baffin Island, through Davis Strait, along the coast of Labrador and Newfoundland, to the Grand Banks, carrying with it large quantities of ice (ch. XXXVI). Here it encounters the warm water of the Gulf Stream, creating the "cold wall." Some of the cold water flows southward along the east coast of North America, inshore of the Gulf Stream, as far as Cape Hatteras. The remainder curves toward the east and flows along the northern edge of the North Atlantic and northeast drift currents, gradually merging with them.

The southeast drift current curves toward the east, southeast, and then south as it is deflected by the coast of Europe. It flows past the Bay of Biscay, toward southeastern Europe and the Canary Islands, where it continues as the **Canary current.** In the vicinity of the Cape Verde Islands, this current divides, part of it curving toward the west to help form the north equatorial current, and part of it curving toward the east to follow the coast of Africa into the Gulf of Guinea, where it is known as the **Guinea current.** This current is augmented by the equatorial countercurrent and, in summer, it is strengthened by monsoon winds. It flows in close proximity to the south equatorial current, but in the opposite direction. As it curves toward the south, still following the African coast, it merges with the south equatorial current.

The clockwise circulation of the North Atlantic leaves a large central area having no well-defined currents. This area is known as the **Sargasso Sea,** from the large quantities of sargasso or gulfweed encountered there.

That branch of the south equatorial current which curves toward the south off the east coast of South America follows the coast as the warm, highly-saline **Brazil current,** which in some respects resembles the Gulf Stream. Off Uruguay, it encounters the colder, less-salty Falkland current and the two curve toward the east to form the broad, slow-moving **South Atlantic current,** in the general vicinity of the prevailing westerlies (art. 3808). This current flows eastward to a point west of the Cape of Good Hope, where it curves northward to follow the west coast of Africa as the strong **Benguela current,** augmented somewhat by part of the Agulhas current flowing around the southern part of Africa from the Indian Ocean. As it continues northward, the current gradually widens and slows. At a point east of St. Helena Island it curves westward to continue as part of the south equatorial current, thus completing the

counterclockwise circulation of the South Atlantic. The Benguela current is augmented somewhat by the **west wind drift,** a current which flows easterly around Antarctica. As the west wind drift flows past Cape Horn, that part in the immediate vicinity of the cape is called the **Cape Horn current.** This current rounds the cape and flows in a northerly and northeasterly direction along the coast of South America as the **Falkland current.**

3207. Pacific Ocean currents follow the general pattern of those in the Atlantic. The **north equatorial current** flows westward in the general area of the northeast trades, and the **south equatorial current** follows a similar path in the region of the southeast trades. Between these two, the weaker **equatorial countercurrent** sets toward the east, just north of the equator.

After passing the Mariana Islands, the major part of the north equatorial current curves somewhat toward the northwest, past the Philippines and Formosa. Here it is deflected further toward the north, where it becomes known as the **Kuroshio,** and then toward the northeast past the Nansei Shoto and Japan, and on in a more easterly direction. Part of the Kuroshio, called the **Tsushima current,** flows through Tsushima Strait, between Japan and Korea, and the Sea of Japan, following generally the northwest coast of Japan. North of Japan it curves eastward and then southeastward to rejoin the main part of the Kuroshio. The limits and volume of the Kuroshio are influenced by the monsoons (art. 3810), being augmented during the season of southwesterly winds, and diminished when the northeasterly winds are prevalent.

The Kuroshio (Japanese for "Black Stream") is so named because of the dark color of its water. It is sometimes called the **Japan Stream.** In many respects it is similar to the Gulf Stream of the Atlantic. Like that current, it carries large quantities of warm tropical water to higher latitudes, and then curves toward the east as a major part of the general clockwise circulation in the northern hemisphere. As it does so, it widens and slows. A small part of it curves to the right to form a weak clockwise circulation west of the Hawaiian Islands. The major portion continues on between the Aleutians and the Hawaiian Islands, where it becomes known as the **North Pacific current.**

As this current approaches the North American continent, most of it is deflected toward the right to form a clockwise circulation between the west coast of North America and the Hawaiian Islands. This part of the current has become so broad that the circulation is generally weak. A small part near the coast, however, joins the southern branch of the Aleutian current, and flows southeastward as the **California current.** The average speed of this current is about 0.8 knot. It is strongest near land. Near the southern end of Baja (Lower) California, this current curves sharply to the west and broadens to form the major portion of the north equatorial current.

During the winter, a weak countercurrent flows northwestward along the west coast of North America from Southern California to Vancouver Island, inshore of the southeasterly flowing California current. This is called the **Davidson current.**

Off the west coast of Mexico, south of Baja California, the current flows southeastward, as a continuation of part of the California current, during the winter. During the summer, the current in this area is northwestward, as a continuation of the equatorial countercurrent, before it turns westward to help form the north equatorial current.

As in the Atlantic, there is in the Pacific a counterclockwise circulation to the north of the clockwise circulation. Cold water flowing southward through the western part of Bering Strait between Alaska and Siberia is joined by water circulating counterclockwise in the Bering Sea to form the **Oyashio.** As the current leaves the strait, it curves toward the right and flows southwesterly along the coast of Siberia and the Kuril Islands. This current brings quantities of sea ice, but no icebergs. When it

encounters the Kuroshio, the Oyashio curves southward and then eastward, the greater portion joining the Kuroshio and North Pacific current. The northern portion continues eastward to join the curving Aleutian current.

As this current approaches the west coast of North America, west of Vancouver Island, part of it curves toward the right and is joined by water from the North Pacific current, to form the California current. The northern branch of the Aleutian current curves in a counterclockwise direction to form the **Alaska current,** which generally follows the coast of Canada and Alaska. When it arrives off the Aleutian Islands, it becomes known as the **Aleutian current.** Part of it flows along the southern side of these islands to about the 180th meridian, where it curves in a counterclockwise direction and becomes an easterly-flowing current, being augmented by the northern part of the Oyashio. The other part of the Aleutian current flows through various openings between the Aleutian Islands, into the Bering Sea. Here it flows in a general counterclockwise direction, most of it finally joining the southerly flowing Oyashio, and a small part of it flowing northward through the eastern side of the Bering Strait, into the Arctic Ocean.

The south equatorial current, extending in width between about 4° N latitude and 10° S, flows westward from South America to the western Pacific. After this current crosses the 180th meridian, the major part curves in a counterclockwise direction, entering the Coral Sea, and then curving more sharply toward the south along the east coast of Australia, where it is known as the **east Australia current.** In the Tasman Sea, northeast of Tasmania, it is augmented by water from the west wind drift, flowing eastward south of Australia. It curves toward the southeast and then the east, gradually merging with the easterly flowing west wind drift, a broad, slow-moving current that circles Antarctica.

Near the southern extremity of South America, most of this current flows eastward into the Atlantic, but part of it curves toward the left and flows generally northward along the west coast of South America as the **Peru current.** Occasionally a set directly toward land is encountered. At about Cabo Blanco, where the coast falls away to the right, the current curves toward the left, past the Galapagos Islands, where it takes a westerly set and constitutes the major portion of the south equatorial current, thus completing the counterclockwise circulation of the South Pacific.

During the northern hemisphere summer, a weak northern branch of the south equatorial current, known as the **Rossel current,** continues on toward the west and northwest along both the southern and northeastern coasts of New Guinea. The southern part flows through Torres Strait, between New Guinea and Australia, into the Arafura Sea. Here, it gradually loses its identity, part of it flowing on toward the west as part of the south equatorial current of the Indian Ocean, and part of it following the coast of Australia and finally joining the easterly flowing west wind drift. The northern part of the Rossel current curves in a clockwise direction to help form the Pacific equatorial countercurrent. During the northern hemisphere winter, the Rossel current is replaced by an easterly flowing current from the Indian Ocean.

3208. Indian Ocean currents follow generally the pattern of the Atlantic and Pacific, but with differences caused principally by the monsoons (art. 3810) and the more limited extent of water in the northern hemisphere. During the northern hemisphere winter, the **north equatorial current** and **south equatorial current** flow toward the west, with the weaker, easterly flowing **equatorial countercurrent** flowing between them, as in the Atlantic and Pacific (but somewhat south of the equator). But during the northern hemisphere summer, both the north equatorial current and the equatorial

countercurrent are replaced by the **monsoon current,** which flows eastward and southeastward across the Arabian Sea and the Bay of Bengal. Near Sumatra, this current curves in a clockwise direction and flows westward, augmenting the south equatorial current and setting up a clockwise circulation in the northern part of the Indian Ocean.

As the south equatorial current approaches the coast of Africa, it curves toward the southwest, part of it flowing through the Mozambique Channel between Madagascar and the mainland, and part flowing along the east coast of Madagascar. At the southern end of this island the two join to form the strong **Agulhas current,** which is analogous to the Gulf Stream.

A small part of the Agulhas current rounds the southern end of Africa and helps form the Benguela current. The major portion, however, curves sharply southward and then eastward to join the west wind drift. This junction is often marked by a broken and confused sea. During the northern hemisphere winter the northern part of this current curves in a counterclockwise direction to form the **west Australia current,** which flows northward along the west coast of Australia. As it passes Northwest Cape, it curves northwestward to help form the south equatorial current. During the northern hemisphere summer, the west Australia current is replaced by a weak current flowing around the western part of Australia as an extension of the southern branch of the Rossel current.

3209. Polar currents.—The waters of the North Atlantic enter the Arctic Ocean between Norway and Svalbard. The currents flow easterly north of Siberia to the region of the Novosibirskiye Ostrova, where they turn northerly across the north pole and continue down the Greenland coast to form the east Greenland current. On the American side of the arctic basin, there is a weak, continuous clockwise flow centered in the vicinity of 80° N, 150° W. A current north through Bering Strait along the American coast is balanced by an outward southerly flow along the Siberian coast, which eventually becomes part of the Oyashio. Each of the main islands or island groups in the arctic, as far as is known, seems to have a clockwise nearshore circulation around it. The Barents Sea, Kara Sea, and Laptev Sea each have a weak counterclockwise circulation. A similar but weaker counterclockwise current system appears to exist in the East Siberian Sea.

In the antarctic, the circulation is generally from west to east in a broad, slow-moving current extending completely around Antarctica. This is called the **west wind drift,** although it is formed partly by the strong westerly wind in this area and partly by density differences. This current is augmented by the Brazil and Falkland currents in the Atlantic, the east Australia current in the Pacific, and the Agulhas current in the Indian Ocean. In return, part of it curves northward to form the Cape Horn, Falkland, and most of the Benguela currents in the Atlantic, the Peru current in the Pacific, and west Australia current in the Indian Ocean.

3210. Ocean currents and climate.—Many of the ocean currents exert a marked influence upon the climate of the coastal regions along which they flow. Thus, warm water from the Gulf Stream, continuing as the North Atlantic, northeast drift, and Irminger currents, arrives off the southwest coast of Iceland, warming it to the extent that Reykjavík has a higher average winter temperature than New York City, far to the south. Great Britain and Labrador are at about the same latitude, but the climate of Great Britain is much milder because of the difference of temperature of currents. The West Coast of the United States is cooled in the summer by the California current, and warmed in the winter by the Davidson current. As a result of this condition, partly, the range of monthly average temperature is comparatively small.

Currents exercise other influences besides those on temperature. The pressure pattern is affected materially, as air over a cold current contracts as it is cooled, and

that over a warm current expands. As air cools above a cold ocean current, fog is likely to form. Frost smoke (art. 3815) is most prevalent over a warm current which flows into a colder region. Evaporation is greater from warm water than from cold water.

In these and other ways, the climate of the earth is closely associated with the ocean currents, although other factors, such as topography and prevailing winds, are also important.

CHAPTER XXXIII

OCEAN WAVES

3301. Introduction.—Undulations of the surface of the water, called **waves**, are perhaps the most widely observed phenomenon at sea, and possibly the least understood by the average seaman. The mariner equipped with a knowledge of the basic facts concerning waves is able to use them to his advantage, and either avoid hazardous conditions or operate with a minimum of danger if such conditions cannot be avoided.

3302. Causes of waves.—Waves on the surface of the sea are caused principally by wind, but other factors, such as submarine earthquakes, volcanic eruptions, and the tide, also cause waves. If a breeze of less than two knots starts to blow across smooth water, small wavelets called **ripples** form almost instantaneously. When the breeze dies, the ripples disappear as suddenly as they formed, the level surface being restored by surface tension of the water. If the wind speed exceeds two knots, more stable **gravity waves** gradually form, and progress with the wind.

While the generating wind blows, the resulting waves may be referred to as **sea**. When the wind stops or changes direction, the waves that continue on without relation to local winds are called **swell.**

Unlike wind and current, waves are not deflected appreciably by the rotation of the earth, but move in the direction in which the generating wind blows. When this wind ceases, friction and spreading cause the waves to be reduced in height, or **attenuated,** as they move across the surface. However, the reduction takes place so slowly that swell continues until it reaches some obstruction, such as a shore.

When sufficient data on wind conditions are available, the swell and state of the sea a day or more in advance can be predicted. Such forecasts have been found useful in wartime offshore unloading operations. The U. S. Navy Hydrographic Office forecasts sea and swell conditions.

3303. Wave characteristics.—Ocean waves are very nearly in the shape of an inverted **cycloid,** the figure formed by a point inside the rim of a wheel rolling along a level surface. This shape is shown in figure 3303a. The highest parts of waves are called **crests,** and the intervening lowest parts, **troughs.** Since the crests are steeper and narrower than the troughs, the mean or still water level is a little lower than halfway between the crests and troughs. The vertical distance between trough and crest is called **wave height,** labeled H in figure 3303a. The horizontal distance between successive crests, measured in the direction of travel, is called **wave length,** labeled L. The time interval between passage of successive crests at a stationary point is called **wave period (P).** Wave height, length, and period depend upon a number of factors, such as the wind speed, the length of time it has blown, and its **fetch** (the straight distance it has traveled over the surface). Table 3303 indicates the relationship between wind speed, fetch, length of time the wind blows, wave height, and wave period in deep water.

TABLE 3303.—Minimum Time (T) in hours that wind must blow to form waves of H significant height (in feet) and P period (in seconds). Fetch in nautical miles. Based upon the relationships given in H.O. Pub. No. 604, *Techniques for Forecasting Wind Waves and Swell.* See also H.O. Pub. No. 603, *Observing and Forecasting Ocean Waves.*

If the water is deeper than one-half the wave length (L), this length in feet is theoretically related to period (P) in seconds by the formula

$$L = 5.12P^2.$$

The actual value has been found to be a little less than this for swell, and about two-thirds the length determined by this formula for sea. When the waves leave the generating area and continue as free waves, the wave length and period continue to increase, while the height decreases. The rate of change gradually decreases.

The speed (S) of a free wave in deep water is nearly independent of its height or steepness. For swell, its relationship in knots to the period (P) in seconds is given by the formula

$$S = 3.03P.$$

The relationship for sea is not known.

The theoretical relationship between speed, wave length, and period is shown in figure 3303b. Thus, as waves continue on beyond the generating area, the period, length, and speed all increase, providing some indication of the distance of the gener-

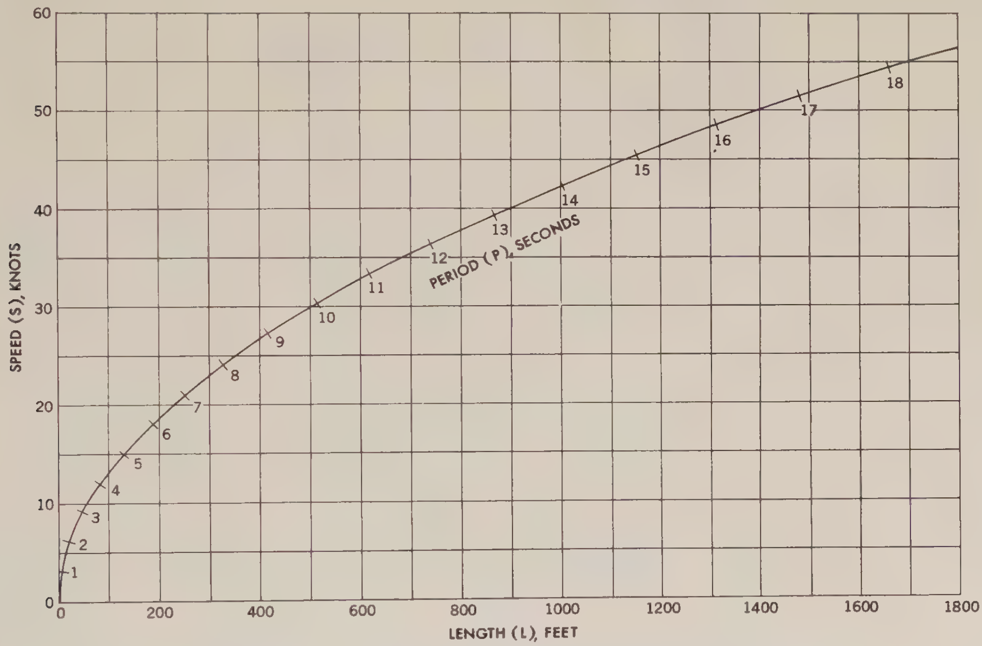

FIGURE 3303b.—Relationship between speed, length, and period of waves in deep water, based upon the theoretical relationship between period and length.

ating area. However, the time needed for a wave system to travel some distance is *double* that which would be indicated by the speed of individual waves. This is because the front wave gradually disappears and transfers its energy to succeeding waves. The process is followed by each front wave in succession, at such a rate that the wave *system* advances at a speed which is just *half* that of *individual* waves. This process can be seen in the bow wave of a vessel. The speed at which the wave system advances is called **group velocity.**

Because of the existence of many independent wave systems at the same time, the sea surface acquires a complex and irregular pattern. Also, since the longer waves outrun the shorter ones, the resulting interference adds to the complexity of the pattern.

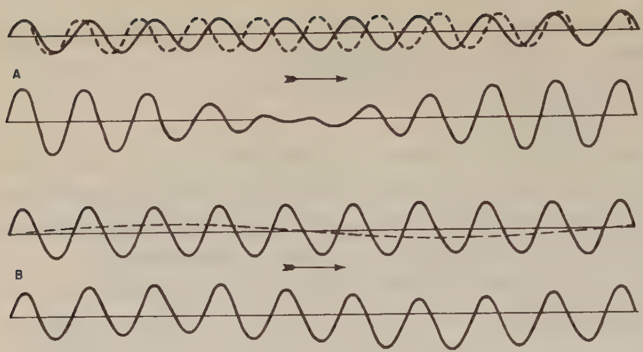

FIGURE 3303c.—Interference. The upper part of *A* shows two waves of equal height and nearly equal length traveling in the same direction. The lower part of *A* shows the resulting wave pattern. In *B* similar information is shown for short waves and long swell.

The process of interference, illustrated in figure 3303c, is duplicated many times in the sea, being the principal reason that successive waves are not of the same height. The irregularity of the surface may be further accentuated by the presence of wave systems crossing at an angle to each other, producing peak-like rises.

In reporting average wave heights, the mariner has a tendency to neglect the lower ones. It has been found that the reported value is about the average for the highest one-third. This is sometimes called the "significant" wave height. The approximate relationship between this height and others, is as follows:

Wave	*Relative height*
Average	0. 64
Significant	1. 00
Highest 10 percent	1. 29
Highest	1. 87

3304. Path of water particles in a wave.—As shown in figure 3304, a particle of water on the surface of the ocean follows a somewhat circular orbit as a wave passes, but moves very little in the direction of motion of the wave. The common wave producing this action is called an **oscillatory wave.** As the crest passes, the particle moves forward, giving the water the appearance of moving with the wave. As the trough passes, the motion is in the opposite direction. The radius of the circular orbit decreases with depth, approaching zero at a depth equal to about half the wave length. In shallower water the orbits become more elliptical, and in very shallow water, as at a beach, the vertical motion disappears almost completely.

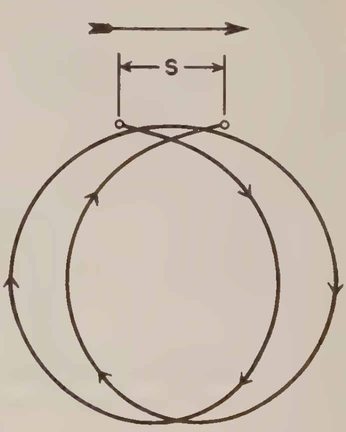

FIGURE 3304.—Orbital motion and displacement, *s*, of a particle on the surface of deep water during two wave periods.

Since the speed is greater at the top of the orbit than at the bottom, the particle is not at exactly its original point following passage of a wave, but has moved slightly in the direction of motion of the wave. However, since this advance is small in relation to the vertical displacement, a floating object is raised and lowered by passage of a wave, but moved little from its original position. If this were not so, a slow moving vessel might experience considerable difficulty in making way against a wave train. In figure 3304 the forward displacement is greatly exaggerated.

3305. Effects of currents on waves.—A following current increases wave lengths and decreases wave heights. An opposing current has the opposite effect, decreasing the length and increasing the height. A strong opposing current may cause the waves

to break. The extent of wave alteration is dependent upon the ratio of the still-water wave speed to the speed of the current.

Moderate ocean currents running at oblique angles to wave directions appear to have little effect, but strong tidal currents perpendicular to a system of waves have been observed to completely destroy them in a short period of time.

3306. The effect of ice on waves.—When ice crystals form in sea water, internal friction is greatly increased. This results in smoothing of the sea surface. The effect of pack ice is even more pronounced. A vessel following a lead through such ice may be in smooth water even when a gale is blowing and heavy seas are beating against the outer edge of the pack. Hail is also effective in flattening the sea, even in a high wind.

3307. Waves and shallow water.—When a wave encounters shallow water, the movement of the individual particles of water is restricted by the bottom, resulting in reduced wave speed. If the wave approaches the shoal at an angle, each part is

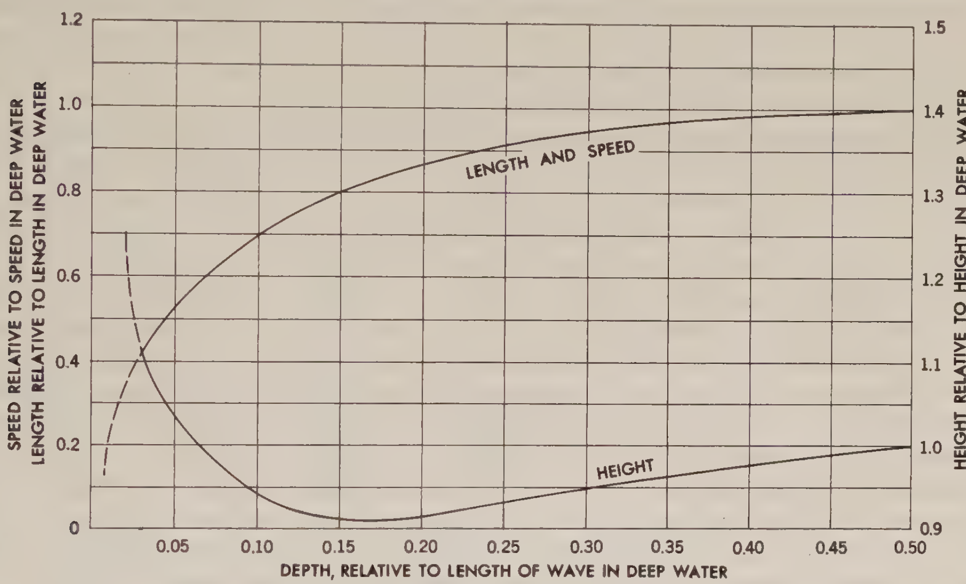

FIGURE 3307.—Alteration of the characteristics of waves as they cross a shoal.

slowed successively as the depth decreases. This causes a change in direction of motion or **refraction,** the wave tending to become parallel to the depth curves. The effect is similar to the refraction of light and other forms of radiant energy (art. 1613).

As each wave slows, the next wave behind it, in deeper water, tends to catch up. As the wave length decreases, the height generally becomes greater. The lower part of a wave, being nearest the bottom, is slowed more than the top. This may cause the wave to become unstable, the faster-moving top falling or **breaking.** Such a wave is called a **breaker,** and a series of breakers, **surf.** This subject is covered in greater detail in chapter XXXIV.

Swell passing over a shoal but not breaking undergoes a decrease in wave length and speed, and an increase in height. Such **ground swell** may cause heavy rolling if it is on the beam and its period is the same as the period of roll of a vessel, even though the sea may appear relatively calm. Figure 3307 illustrates the approximate alteration of the characteristics of waves as they cross a shoal.

3308. Energy of waves.—The potential energy of a wave is related to the vertical distance of each particle from its still-water position, and therefore moves with the

wave. In contrast, the kinetic energy of a wave is related to the speed of the particles, being distributed evenly along the entire wave.

The amount of kinetic energy in even a moderate wave is tremendous. A four-foot, ten-second wave striking a coast expends more than 35,000 horsepower per mile of beach. For each 56 miles of coast, the energy expended equals the power generated at Hoover Dam. An increase in temperature of the water in the relatively narrow **surf zone** in which this energy is expended would seem to be indicated, but no pronounced increase has been measured. Apparently, any heat that may be generated is dissipated to the deeper water beyond the surf zone.

3309. Wave measurement aboard ship.—With suitable equipment and adequate training, one can make reasonably reliable measurements of the height, length, period, and speed of waves. However, the mariner's estimates of height and length usually contain relatively large errors. There is a tendency to underestimate the heights of low waves, and overestimate the heights of high ones. There are numerous accounts of waves 75 to 80 feet high, or even higher, although waves more than 55 feet high are very rare. Wave length is usually underestimated. The motions of the vessel from which measurements are made perhaps contribute to such errors.

Height. Measurement of wave height is particularly difficult. A microbarograph (art. 3705) can be used if the wave is long enough to permit the vessel to ride up and down with it. If the waves are approaching from dead ahead or dead astern, this requires a wave length at least twice the length of the vessel. For most accurate results the instrument should be placed at the center of roll and pitch, to minimize the effects of these motions. Wave height can often be estimated with reasonable accuracy by comparing it with freeboard of the vessel. This is less accurate as wave height and vessel motion increase. If a point of observation can be found at which the top of a wave is in line with the horizon when the observer is in the trough, the wave height is equal to height of eye. However, if the vessel is rolling or pitching, this height at the moment of observation may be difficult to determine.

Length. The dimensions of the vessel can be used to determine wave length. Errors are introduced by perspective and disturbance of the wave pattern by the vessel. These errors are minimized if observations are made from maximum height. Best results are obtained if the sea is from dead ahead or dead astern.

Period. If allowance is made for the motion of the vessel, wave period can be determined by measuring the interval between passages of wave crests past the observer. The correction for the motion of the vessel can be eliminated by timing the passage of successive wave crests past a patch of foam or a floating object at some distance from the vessel. Accuracy of results can be improved by averaging several observations.

Speed can be determined by timing the passage of the wave between measured points along the side of the ship, if corrections are applied for the direction of travel of the wave and the speed of the ship.

More detailed instructions on making wave observations are given in H.O. Pub. No. 606–e, *Sea and Swell Observations*, and H.O. Spec. Pub. 44, *Visual Wave Observations*.

The length, period, and speed of waves in deep waters are interrelated by the relationships indicated in article 3303. However, these should be used as a general guide only, because exact mathematical relationships have not been established, as indicated. In the case of speed and period, there is evidence to indicate that for sea the relationship may be more nearly expressed by the formula $L=SP$ than by that given in article 3303, although there is considerable doubt as to the exact relationship. There is no definite mathematical relationship between wave height and length, period, or speed.

3310. Tsunamis are ocean waves produced by sudden, large-scale motion of a portion of the ocean floor or the shore, as by volcanic eruption, earthquake (sometimes called **seaquake** if it occurs at sea), or landslide. If they are caused by a submarine earthquake, they are usually called **seismic sea waves.** The point directly above the disturbance, at which the waves originate, is called the **epicenter.** Either a tsunami or a storm wave (art. 3311) that overflows the land is popularly called a **tidal wave,** although it bears no relation to the tide.

If a volcanic eruption occurs below the surface of the sea, the escaping gases cause a quantity of water to be pushed upward in the shape of a dome or mound. The same effect is caused by the sudden rising of a portion of the bottom. As this water settles back, it creates a wave which travels at high speed across the surface of the ocean.

Tsunamis usually occur in series, gradually increasing in height until a maximum is reached between about the third and eighth wave. Following the maximum, they again become smaller. Waves may continue to form for several hours, or even for days.

In deep water the wave height of a tsunami is probably never greater than two or three feet. Since the wave length is usually considerably more than 100 miles, the wave is not conspicuous at sea. In the Pacific, where most tsunamis occur, the wave period varies between about 15 and 60 *minutes,* and the speed in deep water is more than 400 knots. The approximate speed can be computed by the formula

$$S=0.6\sqrt{gd}=3.4\sqrt{d},$$

where S is the speed in knots, g is the acceleration due to gravity (32.2 feet per second per second), and d is the depth of water in feet. This formula is applicable to any wave in water having a depth of less than half the wave length. For most ocean waves it applies only in shallow water, because of the relatively short wave length.

When a tsunami enters shoal water, it undergoes the same changes as other waves. The formula indicates that speed is proportional to depth of water. Because of the great speed of a tsunami when it is in relatively deep water, the slowing is relatively much greater than that of an ordinary wave crested by wind. Therefore, the increase in height is also much greater. Tsunamis 50 feet in height or higher have reached the shore, inflicting widespread damage. On April 1, 1946, seismic sea waves originating at an epicenter near the Aleutians spread over the entire Pacific. Scotch Cap Light on Unimak Island, 57 feet above sea level, was completely destroyed. Traveling at an average speed of 490 miles per hour, the waves reached the Hawaiian Islands in four hours and 34 minutes, where they arrived as waves 50 feet above the high water level, and flooded a strip of coast more than 1,000 feet wide at some places. They left a death toll of 173, and property damage of $25,000,000. Less destructive waves reached the shores of North and South America, and Australia, 6,700 miles from the epicenter.

After this disaster, a tsunami warning system was set up in the Pacific, even though destructive waves are relatively rare (averaging about one in 20 years in the Hawaiian Islands). The system consists of three sections. First, a number of seismograph stations to provide information for establishing the time and epicenter of quakes. Second, a group of tide stations to report any evidence of a tsunami. These stations are alerted when a quake is recorded at the seismograph stations. Third, a communication system which gives tsunami warnings high priority because of their speed and possible destructiveness. A travel time chart centered upon the Hawaiian Islands is used to estimate time of arrival of the waves.

Fortunately, relatively few earthquakes produce seismic sea waves. The size of the waves that do form depends upon the nature and intensity of the disturbance. The height and destructiveness of the waves arriving at any place depend upon its distance from the epicenter, topography of the ocean floor, and the coast line itself.

The angle at which the wave arrives, the shape of the coast line, and the topography along the coast and offshore all have their effect. The position of the shore is also a factor, as it may be sheltered by intervening land, or be in a position where waves have a tendency to converge, either because of refraction or reflection, or both.

In addition to seismic sea waves, earthquakes below the surface of the sea may produce a longitudinal wave that travels upward toward the surface, at the speed of sound. When a ship encounters such a wave, it is felt as a sudden shock which may be of such severity that the crew thinks the vessel has struck bottom. Because of such reports, some older charts indicated shoal areas at places where the depth is now known to be a thousand fathoms or more.

3311. Storm waves.—In relatively tideless seas like the Baltic and Mediterranean, winds cause the chief fluctuations in sea level. Elsewhere, the astronomical tide usually masks these variations. However, under exceptional conditions, either severe extratropical storms or tropical cyclones can produce changes in sea level that exceed the normal range of tide. Low sea level is of little concern except to shipping, but a rise above ordinary high-water mark, particularly when it is accompanied by high waves, can result in a catastrophe.

Although, like tsunamis, these **storm waves** or **storm surges** are popularly called **tidal waves,** they are not associated with the tide. They consist of a single wave crest and hence have no period or wave length.

Three effects in a storm induce a rise in sea level. The first is wind stress on the sea surface, which results in a piling-up of water (sometimes called "wind set-up"). The second effect is the convergence of wind-driven currents, which elevates the sea surface along the convergence line. In shallow water, bottom friction and the effects of local topography cause this elevation to persist and may even intensify it. The low atmospheric pressure that accompanies severe storms causes the third effect, which is sometimes referred to as the "inverted barometer." An inch of mercury is equivalent to about 13.6 inches of water (art. 3115) and the adjustment of the sea surface to the reduced pressure can amount to several feet at equilibrium (art. 3911).

All three of these causes act independently, and if they happen to occur simultaneously, their effects are additive. In addition, the wave can be intensified or amplified by the effects of local topography. Storm waves may reach heights of 20 feet or more, and it is estimated that they cause three-fourths of the deaths attributed to hurricanes.

3312. Standing waves and microseisms.—Previous articles in this chapter have dealt with **progressive waves** which appear to move regularly with time. When two systems of progressive waves having the same period travel in opposite directions across the same area, a series of **standing waves** may form. These appear to remain stationary. Recent investigation has indicated that when this condition occurs, a pressure variation is exerted on the ocean bottom proportional to the product of the wave heights of the two wave systems. The period of these pressure variations is half that of the progressive waves. The magnitude and period of these variations are of the right order to cause a series of minute earth shocks of the magnitude of those recorded by very sensitive seismographs and known as **microseisms.** It is probable, therefore, that microseisms are generated by standing waves established in any manner, as by waves from independent sources, those in the wake of a moving circulation, waves at the center of a stationary circulation, or by reflection of waves striking a steep shore.

Another type of standing wave, called a **seiche** (sāsh), sometimes occurs in a confined body of water. It is a long wave, usually having its crest at one end of the confined space, and its trough at the other. Its period may be anything from a few

minutes to an hour or more, but somewhat less than the tidal period. Seiches are usually attributed to strong winds or differences in atmospheric pressure.

3313. Tide waves.—As indicated in chapter XXXI, there are, in general, two regions of high tide separated by two regions of low tide, and these regions move progressively westward around the earth as the moon revolves in its orbit. The high tides are the crests of these **tide waves,** and the low tides are the troughs. The wave is not noticeable at sea, but becomes apparent along the coasts, particularly in funnel-shaped estuaries. In certain river mouths or estuaries of particular configuration, the incoming wave of high water overtakes the preceding low tide, resulting in a high-crested, roaring wave which progresses upstream in one mighty surge called a **bore.**

3314. Internal waves.—Thus far, the discussion has been confined to waves on the surface of the sea, the boundary between air and water. **Internal waves,** or **boundary waves,** are created below the surface, at the boundaries between water strata of different densities. The density differences between adjacent water strata in the sea are considerably less than that between sea and air. Consequently, internal waves are much more easily formed than surface waves, and they are often much larger. The maximum height of wind waves on the surface is about 60 feet, but internal wave heights as great as 300 feet have been encountered.

Internal waves are detected by a number of observations of the vertical temperature distribution, using recording devices such as the bathythermograph (art. 3007). They have periods as short as a few minutes, and as long as 12 or 24 hours, these greater periods being associated with the tides.

A slow-moving ship operating in a fresh water layer having a depth approximating the draft of the vessel may produce short-period internal waves. This may occur off rivers emptying into the sea or in polar regions in the vicinity of melting ice. Under suitable conditions, the normal propulsion energy of the ship is expended in generating and maintaining these internal waves and the ship appears to "stick" in the water, becoming sluggish and making little headway. The phenomenon, known as **dead water,** disappears when speed is increased by a few knots.

The full significance of internal waves has not been determined, but it is known that they may cause submarines to rise and fall like a ship at the surface, and they may also affect sound transmission in the sea.

3315. Waves and ships.—The effects of waves on a ship vary considerably with the type ship, its course and speed, and the condition of the sea. A short vessel has a tendency to ride up one side of a wave and down the other side, while a larger vessel may tend to ride *through* the waves on an even keel. If the waves are of such length that the bow and stern of a vessel are alternately in successive crests and successive troughs, the vessel is subject to heavy sagging and hogging stresses, and under extreme conditions may break in two. A change of heading may reduce the danger. Because of the danger from sagging and hogging, a small vessel is sometimes better able to ride out a storm than a large one.

If successive waves strike the side of a vessel at the same phase of successive rolls, relatively small waves can cause heavy rolling. The effect is similar to that of swinging a child, where the strength of the push is not as important as its timing. The same effect, if applied to the bow or stern in time with the pitch, can cause heavy pitching. A change of either heading or speed can reduce the effect.

A wave having a length twice that of a ship places that ship in danger of falling off into the trough of the sea, particularly if it is a slow-moving vessel. The effect is especially pronounced if the sea is broad on the bow or broad on the quarter. An increase of speed reduces the hazard.

3316. Use of oil for modifying the effects of breaking waves.—Oil has proved effective in modifying the effects of breaking waves, and has proved useful to vessels at sea, whether making way or stopped, particularly when lowering or hoisting boats. Its effect is greatest in deep water, where a small quantity suffices if the oil can be made to spread to windward. In shallow water where the water is in motion over the bottom, oil is less effective but of some value.

The heaviest oils, notably animal and vegetable oils, are the most effective. Crude petroleum is useful, but its effectiveness can be improved by mixing it with animal and vegetable oils. Gasoline or kerosene are of little value. Oil spreads slowly. In cold weather it may need some thinning with petroleum to hasten the process and produce the desired spread before the vessel is too far away for the effect to be useful.

At sea, best results can be expected if the vessel drifts or runs slowly before the wind, with the oil being discharged on both sides from waste pipes or by other convenient method. If a sea anchor is used, oil can be distributed from a container inserted within it for this purpose. If such a container is not available, an oil bag can be fastened to an endless line rove through a block on the sea anchor. This permits distribution of oil to windward, and provides a means for hauling the bag aboard for refilling. If another vessel is being towed, the oil should be distributed from the towing vessel, forward and on both sides, so that both vessels will be benefited. If a drifting vessel is to be approached, the oil might be distributed from both sides of the drifting vessel or by the approaching vessel, which should distribute it to leeward of the drifting vessel so that that vessel will drift into it. If the vessel being approached is aground, the procedure best suiting the circumstances should be used.

If oil is needed in crossing a bar to enter a harbor, it can be floated in ahead of the vessel if a flood current is running. A considerable amount may be needed. During slack water a hose might be trailed over the bow and oil poured freely through it if no more convenient method is available. With an ebb current oil is of little use, unless it can be distributed from another vessel or in some other manner from the opposite side of the bar.

CHAPTER XXXIV

AMPHIBIOUS OPERATIONS

3401. Amphibious operations and the navigator.—Among the major problems in amphibious operations are the safe navigation of landing craft through the surf zone to the beach, trafficability of the beach, and movement inland. The purpose of this chapter is to acquaint the navigator with the first two of these and the oceanographic factors affecting them. The navigational aspects of the third problem are discussed in chapter XXVII, "Land Navigation."

3402. Refraction.—As explained in article 3307, wave speed is slowed in shallow water, causing **refraction** if the waves approach the beach at an angle. Along a perfectly straight beach, with uniform shoaling, the wave fronts tend to become parallel to the shore. Any irregularities in the coast line or bottom contours, however, affect the refraction, causing irregularity. In the case of a ridge perpendicular to the beach, for instance, the shoaling is more rapid, causing greater refraction. The waves tend to align themselves with the bottom contours. Waves on both sides of the ridge have a component of motion toward the ridge. This **convergence** of water toward the ridge causes an increase in wave or breaker height. A submarine canyon or valley perpendicular to the beach, on the other hand, produces **divergence,** with a decrease in wave or breaker height. These effects are illustrated in figure 3402. Bends in the coast line have a similar effect, convergence occuring at a *point,* and divergence if the coast is concave to the sea.

Under suitable conditions, currents also cause refraction. This is of particular importance at entrances of tidal estuaries. When waves encounter a current running in the opposite direction, they become higher and shorter. This results in a choppy

FIGURE 3402.—The effect of bottom topography in causing wave convergence and wave divergence.

sea, often with breakers. When waves move in the same direction as current, they decrease in height, and become longer. Refraction occurs when waves encounter a current at an angle.

Refraction diagrams, useful in planning amphibious operations, can be prepared with the aid of nautical charts or aerial photographs. The method of doing so is explained in H.O. Pub. No. 605, *Graphical Construction of Wave Refraction Diagrams.*

3403. Breakers and surf.—In deep water, swell generally moves across the surface as somewhat regular, smooth undulations (ch. XXXIII). When shoal water is reached, the wave period remains the same, but the speed decreases. The amount of decrease is negligible until the depth of water becomes about one-half the wave length, when the waves begin to "feel" bottom. There is a slight decrease in wave height, followed by a rapid increase, if the waves are traveling perpendicular to a straight coast with a uniformly sloping bottom. As the waves become higher and shorter, they also become steeper, and the crest becomes narrower. When the speed of individual particles at the crest becomes greater than that of the wave, the front face of the wave becomes steeper than the rear face. This process continues at an accelerating rate as the depth of water decreases. At some point the wave may become unstable, toppling forward to form a **breaker.**

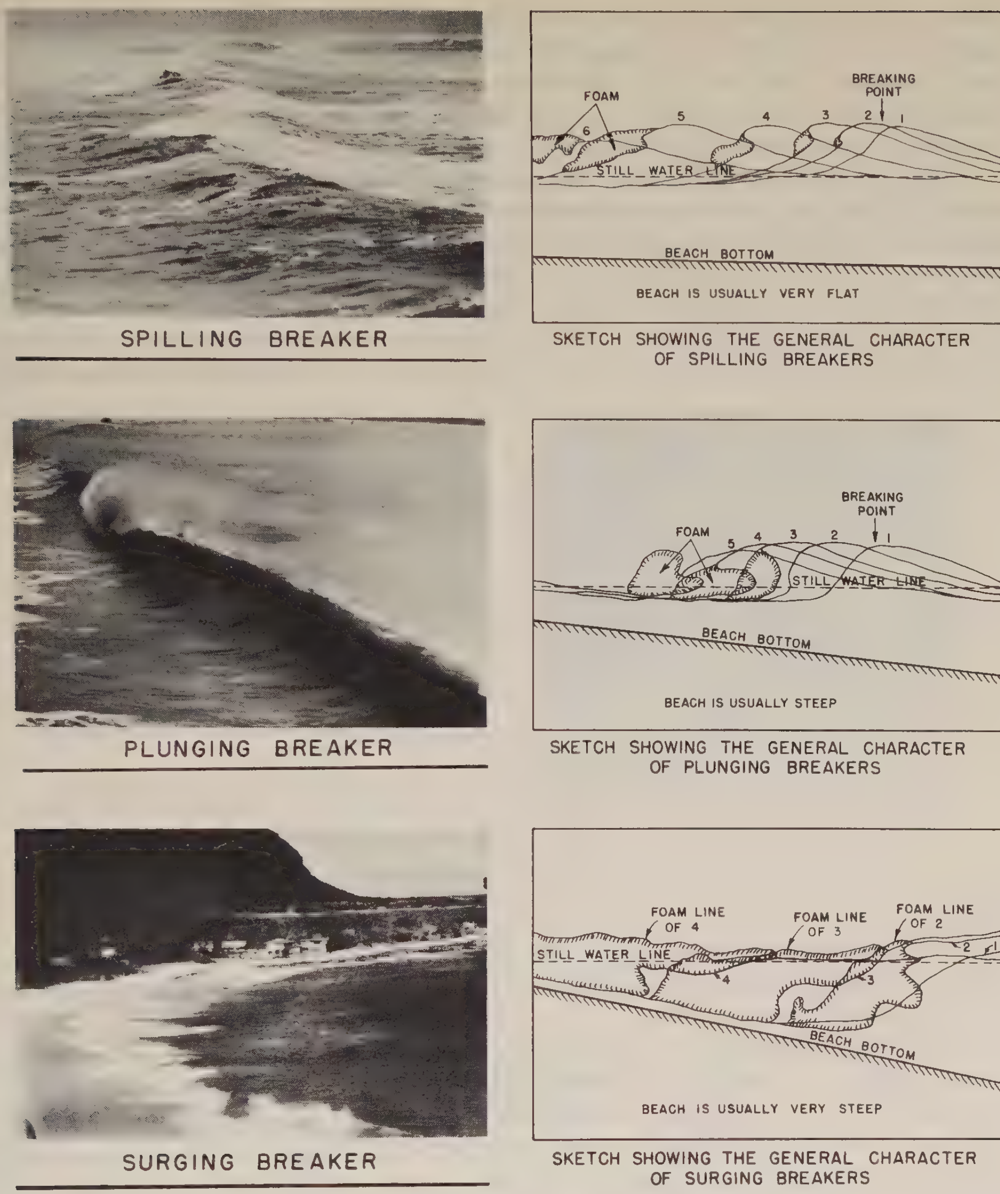
There are three general classes of breakers. A **spilling breaker** breaks gradually over a considerable distance. A **plunging breaker** tends to curl over and break with a single crash. A **surging breaker** peaks up, but surges up the beach without spilling or plunging. It is classed as a breaker even though it does not actually break. The type of breaker is determined by the steepness of the beach and the steepness of the wave before it reaches shallow water, as illustrated in figure 3403.

Longer waves break in deeper water, and have a greater breaker height. The effect of a steeper beach is also to increase breaker height. The height of breakers is less if the waves approach the beach at an acute angle. With a steeper beach slope there is greater tendency of the breakers to plunge or surge. Following the **uprush** of water onto a beach after the breaking of a wave, the seaward **backrush** occurs. The returning water is called **backwash.** It tends to further slow the bottom of a wave, thus increasing its tendency to break. This effect is greater as either the speed or depth of the backwash increases. The still water depth at the point of breaking is approximately 1.3 times the average breaker height.

Surf varies with both position along the beach and time. A change in position often means a change in bottom contour, with the refraction effects discussed in article 3402. At the same point, the height and period of waves vary considerably from wave to wave. A group of high waves is usually followed by several lower ones. Therefore, passage through surf can usually be made most easily immediately following a series of higher waves.

Since surf conditions are directly related to height of the waves approaching a beach, and the configuration of the bottom, the state of the surf at any time can be predicted if one has the necessary information and knowledge of the principles involved. Height of the sea and swell can be predicted from wind data, and information on bottom configuration can generally be obtained from the nautical chart. In addition, the area of lightest surf along a beach can be predicted if details of the bottom configuration are available. Detailed information on prediction of surf conditions is given in H.O. Pub. No. 234, *Breakers and Surf; Principles in Forecasting.*

3404. Currents in the surf zone.—In and adjacent to the surf zone, currents are generated by waves approaching the bottom contours at an angle, and by irregularities in the bottom.



Courtesy of Robert L. Weigel, Council on Wave Research, University of California.

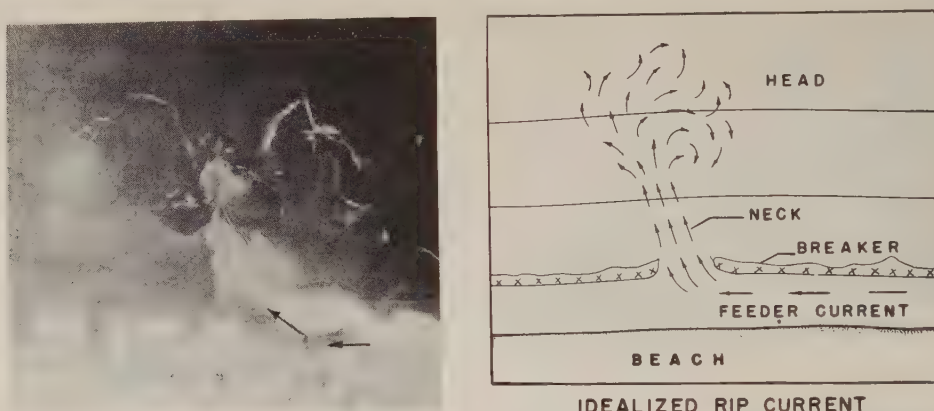
FIGURE 3403.—The three types of breakers.

Waves approaching at an angle produce a **longshore current** parallel to the beach, within the surf zone. Longshore currents are most common along straight beaches. Their speeds increase with increasing breaker height, decreasing wave period, increasing angle of breaker line with the beach, and increasing beach slope. Speed seldom exceeds one knot, but sustained speeds as high as three knots have been recorded. Longshore currents are usually constant in direction. They increase the danger of landing craft broaching to.

As explained in article 3402, wave fronts advancing over nonparallel bottom contours are refracted to cause convergence or divergence of the energy of the waves. Energy concentrations, in areas of convergence, form barriers to the returning back-

wash, which is deflected *along* the beach to areas of less resistance. Backwash accumulates at weak points, and returns seaward in concentrations, forming **rip currents** through the surf. At these points the large volume of returning water has a retarding effect upon the incoming waves, thus adding to the condition causing the rip current. The waves on one or both sides of the rip, having greater energy and not being retarded by the concentration of backwash, advance faster and farther up the beach. From here, they move *along* the beach as **feeder currents.** At some point of low resistance, the water flows seaward through the surf, forming the **neck** of the rip current. Outside the breaker line the current widens and slackens, forming the **head.** The various parts of a rip current are shown in figure 3404.

Rip currents may also be caused by irregularities in the beach face. If a beach indentation causes an uprush to advance farther than the average, the backrush is



Courtesy of Robert L. Weigel, Council on Wave Research, University of California.

FIGURE 3404.—A rip current (left) and a diagram of its parts (right).

delayed and this in turn retards the next incoming **foam line** (the front of a wave as it advances shoreward after breaking) at that point. The foam line on each side of the retarded point continues in its advance, however, and tends to fill in the retarded area, producing a rip current.

3405. Beach trafficability.—The trafficability of an area depends upon characteristics of both the area itself and the vehicles to be used in traversing the area.

In amphibious operations, landing craft must successively negotiate the submerged section of the beach between landing craft and shore, the moist "beach face" which is covered by water at high tide, the dry section which is never submerged, and the backshore. Several types and conditions of soils may be encountered in traversing the four sections.

Bearing capacity, traction capacity, and **rolling resistance** are the main factors in soil trafficability. Bearing capacity concerns the ability of the soil to support the vehicle; traction capacity deals with its ability to give the vehicle a forward thrust; rolling resistance refers to the tendency of the soil to oppose the forward thrust. These main factors are themselves dependent upon vehicle characteristics, traffic density, slope of the ground, nature of the soil, and certain soil characteristics which depend chiefly upon the water content of the soil.

Trafficability investigations have led to the following general conclusions: (1) Serious trafficability problems arise with mud. (2) The trafficability of sandy beaches composed of coarse-grained soils increases with increased flatness. The bearing and traction capacities of such soils are satisfactory if the soil is confined, as by the use of large low-pressure tires or wide tracks. (3) Wet sand offers less resistance than dry

sand. Therefore, vehicles are best discharged at low tide, onto the moist part of the beach face thus exposed. Vehicles landed after a heavy rain will encounter better trafficability than those landed when the beach is dry. (4) The landing of tracked vehicles on all but the flattest beaches disturbs the soil to such an extent that wheeled vehicles have great difficulty in operating. However, tracked vehicles can operate on many beaches where wheeled vehicles cannot be used under any circumstances.

When a beach is insufficiently stable to support sustained traffic from landing craft to backshore, artificial means may be used to increase the stability. The three general methods are (1) densification of the soil, (2) addition of cementing agents, and (3) elimination of excess moisture and the prevention of moisture accumulation. Another approach is to bring vehicles ashore by means of pontoon causeways, landing mats, or other types of temporary roadways.

CHAPTER XXXV

SOUND IN THE SEA

3501. Underwater sound and the navigator.—The clarity with which the noises associated with weighing anchor, propelling a ship, and other underwater motions are heard below the water line and near the skin of a vessel is an indication of the high sound-transmitting qualities of sea water. Water is a better conductor of sound than is air because it absorbs less energy from the sound. There are several ways in which underwater sound can be used in navigation.

The *direction* of travel of sound waves can be measured either by means of **binaural hearing** (hearing with two "ears"), or by equipment which has directional characteristics similar to those of a directional antenna used in radio (art. 1012). Either method can be used for determining the direction from which general noise is coming, but only the latter is used in sonar equipment (art. 1108) for determining direction and distance by reception of an echo from a directional signal, in a manner similar to radar (art. 1208).

Distance can be determined by (1) measuring the elapsed time between transmission of a signal and return of its echo, (2) measuring the elapsed time between transmission of a signal and its receipt at a second station, (3) measuring the time *difference* between reception of a signal transmitted through water and one transmitted through air, (4) measuring the difference in phase between two signals or change of phase of a signal when it returns as an echo, or (5) measuring the angle at which an echo is received from a signal produced at another place. The first method, used in sonar (art. 1108) and echo sounding equipment (art. 619), is similar in principle to radar (art. 1208). The second method is used primarily in RAR (art. 1205), in which underwater sound signals trigger a "sonobuoy," which transmits a radio signal to indicate the time of reception of the sound signal. The third method is used at distance finding stations (art. 1205). The fourth and fifth methods were used in early forms of echo sounders.

The *difference* in time of reception of the same signal at two or more points is used in sofar (art. 1313) in a manner which is similar but reversed to that of loran (art. 1302).

3502. Sources of sound in the ocean.—Underwater sounds intended for navigational use are produced in one of three basic ways: (1) by percussion, as the striking of a bell, gong, or the bottom of the vessel; (2) by oscillator, as the vibration of a diaphragm; (3) by explosion, as by small bomb or depth charge. Certain man-made noises ordinarily produced in water, such as those due to operation of the main engines of a vessel, can be detected by an appropriate listening device.

In addition, many noises are made by animals living in the ocean. Certain shrimp, great numbers of which inhabit some areas, make a snapping noise with their claws. Some fish make a noise by stridulating (scraping). When shellfish are being eaten, a sound is emitted as the shells are broken by the teeth of the fish which are feeding. Grunting noises are made by many kinds of fish, usually by means of their swim bladders. Porpoises produce sounds of a high pitch. Sounds of various frequency and amplitude are produced by other forms of marine life. Where sound-producing marine life is very abundant, it interferes with detection of man-made

sounds, requiring a high signal-to-noise ratio. The effect is similar to that of a high atmospheric noise level in radio.

3503. Speed of sound in sea water.—Three variables govern the speed (S) of sound in a fluid. They are density (ρ), compressibility (β), and the ratio between the specific heats of the fluid at constant pressure and at constant volume (γ). The following formula is sufficiently accurate for most navigational purposes:

$$S=\sqrt{\frac{\gamma}{\rho\beta}}.$$

Density and specific heat are discussed in articles 3009 and 3012, respectively. Compressibility refers to the relative change in volume for a given change in pressure. The compressibility of water is low, and consequently the speed of sound in water is high. The specific heat ratio enters the formula because the energy of a sound impulse is briefly transformed into heat, and then reconverted (with slight loss) into kinetic energy. The ratio rarely exceeds 1.02 in sea water and is commonly taken as unity.

For atmospheric pressure 29.92 inches of mercury, temperature 60° F, and salinity 34.85 parts per thousand, the density of sea water is 64 pounds per cubic foot and the compressibility approximately 0.0000435 per atmosphere (one atmosphere equals 14.696 pounds per square inch). Using these values and 32.174 feet per second per second (the acceleration of gravity at latitude 45°) and 144 square inches per square foot, and taking γ equal to unity, one obtains:

$$S=\sqrt{\frac{1.0\times 32.174\times 14.696\times 144}{64\times 0.0000435}}=4945 \text{ ft./sec.}$$

The same formula can be used to determine the speed of sound in air. For atmospheric pressure 29.92 and temperature 60° F, the density of air is 0.0764 pound per cubic foot and, since air is a gas, the compressibility is the reciprocal of the pressure. Taking γ equal to 1.4, one obtains:

$$S=\sqrt{\frac{1.4\times 32.174\times 14.696\times 144}{0.0764\times 1}}=1117 \text{ ft./sec.}$$

The speed of sound in water is approximately 4.5 times its speed in air.

An increase in temperature decreases both density and compressibility, resulting in an increase in the speed of sound. In sea water, an increase in pressure or salinity produces a slight increase in density and a larger decrease in compressibility, resulting in a net increase in the speed of sound. Thus, in sea water, an increase in temperature, pressure, or salinity results in greater speed of sound. Of the three, temperature has the greatest influence on the speed of sound in sea water in the upper layers. At depth, pressure, and in coastal areas, changes in salinity, may have the greatest effect.

Normally, the change of these three elements is much more rapid in a vertical direction than in a horizontal direction. The change with depth varies with location. With respect to temperature, much of the ocean is considered to consist of three layers, a **surface layer** influenced greatly by the temperature of the air above it, a **thermocline** of rapidly decreasing temperature, and a nearly uniform **deep-water layer.** Typical curves showing change of temperature and salinity with depth are shown in figure 3503a. The increase of pressure with depth is almost uniform, the pressure at 10,000 feet being approximately twice that at 5,000 feet, and ten times that at 1,000 feet. A typical curve of speed of sound with depth is shown in figure 3503b. The speeds for all temperature, pressure, and salinity conditions encountered in the sea are given in *Tables of*

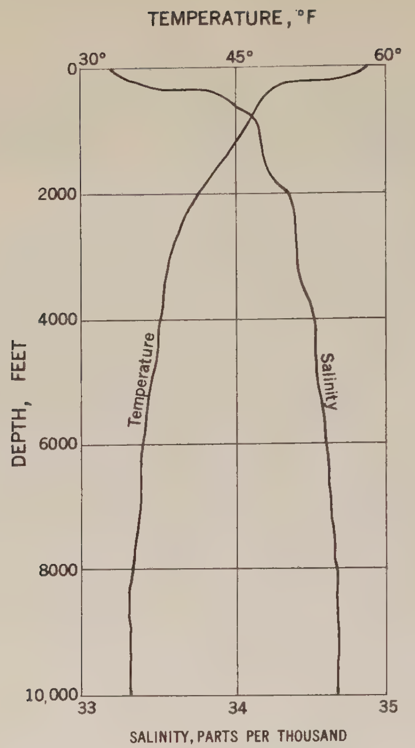


FIGURE 3503a.—Variation of temperature and salinity with depth at one locality.

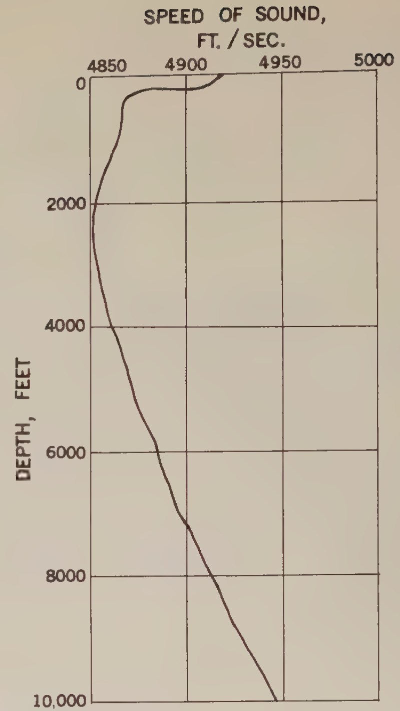

FIGURE 3503b.—Typical variation of speed of sound with depth in the ocean.

Sound Speed in Sea Water, SP 58, published by the U.S. Navy Hydrographic Office.

Study of transmission of sound from underwater explosions indicates that near the explosion the speed of sound may be somewhat higher than expected, probably due to increased pressure caused by the disturbance. This effect extends over such a short distance that it is insignificant in ordinary underwater sound transmission.

3504. Reflection of underwater sound waves.—In water, as in air, sound is reflected by obstructions in the form of solid objects or sharp discontinuities. Thus, sound is reflected from the bottom, the shore, hulls of ships, the surface of the water, etc. It is this reflecting energy that is used in echo sounders (art. 619) to determine depth, and in sonar equipment (art. 1108) used for echo ranging.

Reflecting properties of various substances differ markedly. Rock reflects almost all of the sound that strikes its surface, while soft mud absorbs or is penetrated by sound. Thus, in echo sounding, a layer of soft mud over rock may result in two echoes, indicating two depths.

Fish and even tiny sea animals also reflect sound. As a result, echo sounders are widely used among fishermen to locate schools of fish. In deep water it is not unusual for an echo sounder to receive an echo from a depth of about 200 fathoms, although the depth decreases somewhat at night. This **phantom bottom** or **deep scattering layer,** which is undoubtedly the source of many erroneous shoal sounding reports, is believed to be due to large numbers of tiny marine animals, or other marine life.

A sharp discontinuity within the water causes reflection of sound. Thus, an echo sounder may detect the boundary between a layer of fresh water overlying salt water, a condition which might occur near the mouth of a river.

Sharp, distinct echoes denoting precise depths are difficult to obtain over rough-surfaced bottoms. Therefore, considerable discretion should be exercised in evaluating soundings taken over bottoms possessing a high degree of relief.

3505. Refraction of underwater sound waves.—The laws of refraction as applied to light (art. 1613) and radio waves (art. 1006) apply also to sound. Because of differences of speed of sound in sea water, an advancing sound wave is refracted toward the area of slower speed. If sound is traveling vertically downward, as in echo sounding, the effect of refraction is relatively slight because the layers of water in which speed differs are approximately horizontal, and when the direction of travel of the sound is normal to the refracting surface or layer, there is no refraction.

When a *beam* of sound is directed in a horizontal direction, however, refraction is greatest. If the speed *decreases* with depth, the usual situation, the upper part of the beam travels faster than the lower part, and the beam is diverted downward, leaving a **shadow zone** near the surface in which the sound does not enter, except for a weak signal due to scattering. If the speed *increases* with depth, the lower part moves faster, and the beam is deflected upward toward the surface, where part of it is reflected, part moves along the surface with some scattering if the surface is not smooth, and part (less than 1%) is lost to the air.

With typical distribution of speed with depth, as shown in figure 3503b, speed decreases with depth until a minimum is reached at some level below the surface, and below this the speed increases. In figure 3503b minimum speed occurs at about 2,400 feet. In the tropics this level of minimum speed may be as deep at 6,000 feet, and in polar regions it may be at the surface. Sound produced at any level tends to be refracted to the level of minimum speed, and to remain there, for as it attempts to leave this level, it is refracted back toward it, as shown in figure 3505. This, of course, does not refer to sound traveling vertically. If a sound is produced at this level, as by the explosion of a bomb or depth charge, the sound waves start to move outward as expanding spheres, but most of the rays are refracted back toward the minimum speed level. Because of this effect, such a sound may travel great distances with relatively little decrease in intensity. Listening gear placed at this level has detected sounds produced thousands of miles away. This is the principle used in **sofar** (art. 1313).

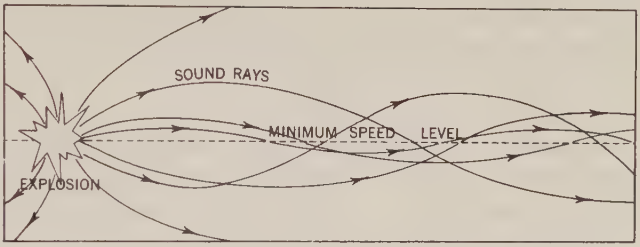

FIGURE 3505.—Transmission of sound rays along the minimum sound level.

CHAPTER XXXVI

ICE IN THE SEA

3601. Ice and the navigator.—The perpetually frozen Arctic Ocean and the solid sheet of ice beneath which Antarctica is buried offer evidence that the earth has not yet completely emerged from its most recent Ice Age. Each winter this polar ice increases and spreads toward more temperate latitudes, and each summer it contracts again as part of the ice melts. Some of the fragments are carried by ocean currents into shipping lanes, forming a major hazard to shipping. There is evidence to indicate that the polar regions are becoming warmer. Nearly all glaciers are receding; the ice shelves off northern Canada and Greenland are breaking up; shipping off the Siberian coast has become possible; cod are found ever farther north along the Greenland coast.

Ice is of direct concern to the navigator because it restricts and sometimes controls his movements, it affects his dead reckoning by forcing frequent and sometimes inaccurately determined changes of course and speed, it affects his piloting by altering the appearance or obliterating the features of landmarks and by rendering difficult the establishment and maintenance of aids to navigation, it affects his electronic navigation by its effect upon propagation of radio waves and the changes it produces both in surface features and radar returns from such features, it affects his celestial navigation by altering the refraction and obscuring his horizon and celestial bodies either directly or by the weather it influences, and it affects his charts by introducing various difficulties to the hydrographic surveyor.

Because of his direct concern with ice, the prospective polar navigator will do well to acquaint himself with its nature and extent in the area he expects to navigate. To this end he should consult the sailing directions for the area, and whatever other literature may be available to him, including reports of previous operations in the same area.

3602. Formation of ice.—As it cools, water contracts until the temperature of maximum density is reached. Further cooling results in expansion. The maximum density of fresh water occurs at a temperature of 39°2 F, and freezing takes place at 32° F. The addition of salt lowers both the temperature of maximum density and, to a lesser extent, that of freezing. The relationships are shown in figure 3602. The two lines meet at a salinity of 24.7 parts per thousand, at which maximum density occurs at the freezing temperature of 29°61 F. At this and greater salinities, the density increases right down to the freezing point. At a salinity of 35 parts per thousand, the approximate average for the oceans, the freezing point is 28°6 F.

Generally, ice forms first at the water surface. As it does, most of the dissolved solids remain in the water, beneath the ice, increasing the density of the water there. This lowers the freezing point, thus tending to retard the freezing process. It is further retarded by the fact that ice is a poor conductor of heat and therefore serves as an insulator to protect the water from colder air above.

In shoal water and streams, particularly where motion is sufficient to cause thorough mixing, the freezing temperature may extend from the surface to the bottom. When this occurs, ice crystals may form at any depth. Because of their decreased density, they tend to rise to the surface, unless they form at the bottom and attach themselves

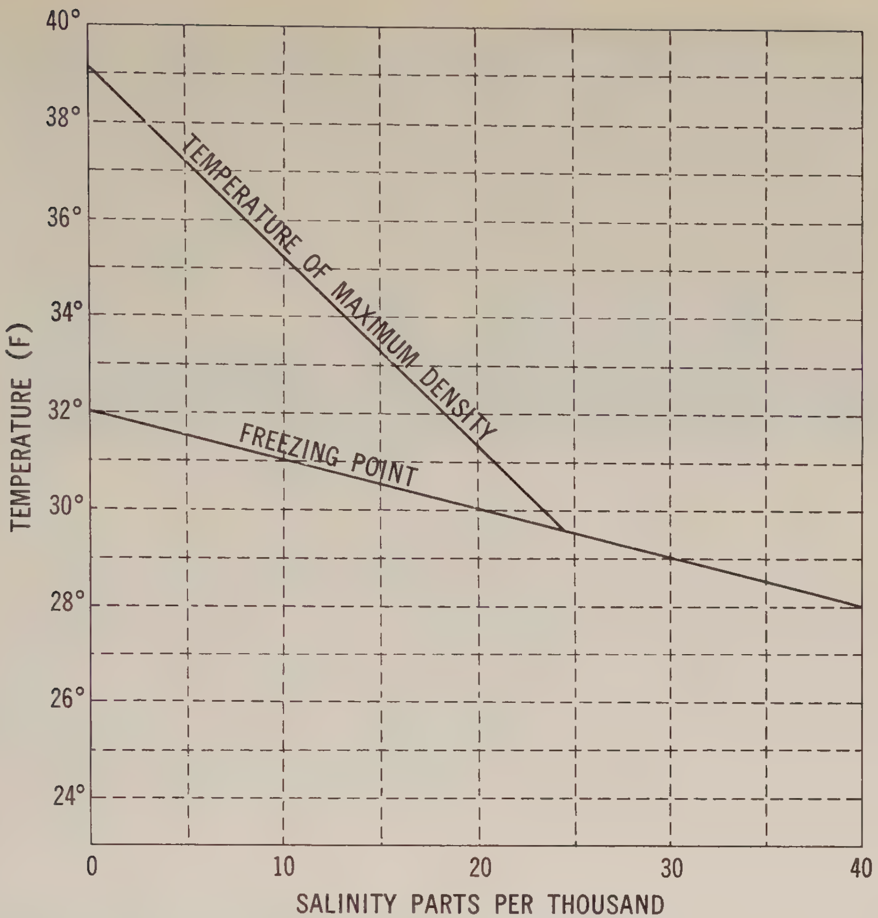

FIGURE 3602.—Relationship between temperature of maximum density and freezing point for water of varying salinity.

there. This **bottom ice,** sometimes called **anchor ice,** continues to grow as additional ice freezes to that already formed.

Ice may also be formed by the compacting of fallen snow, or by the freezing of a mixture of snow and sea water.

3603. Land ice is formed on land by the freezing of fresh water or the compacting of snow as layer upon layer adds to the pressure on that beneath. As snow becomes hardened by wind, temperature, and pressure, it reaches an intermediate stage when it is known as **névé** (nā′vā′).

Under great pressure ice becomes slightly plastic and is forced outward and downward along an inclined surface. If a large area is relatively flat, as on the antarctic plateau, or if the outward flow is obstructed, as on Greenland, an **ice cap** forms and remains winter and summer, in some places reaching depths of several thousand feet. Where ravines or mountain passes permit flow of the ice, a **glacier** is formed. This is a slow-moving river of ice that flows to lower levels, exhibiting many of the characteristics of rivers of water. The flow may be more than 100 feet per day, but is generally much less. When a glacier reaches a comparatively level area, it spreads out. When a glacier flows into the sea, the buoyant force of the water breaks off pieces from time to time, and these float away as **icebergs.**

An iceberg seldom melts uniformly because of lack of uniformity in the ice itself, differences in the temperature above and below the water line, exposure of one side to

the sun, strains, cracks, mechanical erosion, etc. The inclusion of rocks, silt, and other foreign matter further accentuates the differences. As a result, changes in equilibrium take place, which may cause the berg to tilt or capsize. Parts of it may break off or **calve,** forming separate, smaller bergs. A small berg about the size of a house is called a **bergy bit,** and one still smaller but large enough to inflict serious damage to a vessel is called a **growler** because of the noise it sometimes makes as it bobs up and down in the sea. Bergy bits and growlers are usually pieces calved from icebergs, but they may be formed by consolidation of sea ice or by the melting of an iceberg. The principal danger from icebergs is their tendency to break or shift position, and possible underwater extensions, called **rams.**

3604. Sea ice forms by the freezing of sea water. The first indication is a greasy or oily appearance of the surface, with a peculiar gray or leaden tint. The small individual particles of ice, called **spicules,** then become visible. As the number increases, the mixture of water and ice is soupy or mushy, having about the consistency of wet snow. At this stage it is called **slush.** The height of waves is noticeably reduced. As the individual particles freeze together, a thin layer of highly plastic ice forms. This bends easily and moves up and down with the waves. A layer of two inches of fresh-water ice is brittle but strong enough to support the weight of a heavy man. In contrast, the same thickness of newly formed sea ice will support not more than about ten percent of this weight, although its strength varies with the temperature at which it is formed, very cold ice supporting a greater weight than warmer ice. When snow falls into sea water which is near its freezing point, but colder than the melting point of snow, it does not melt, but floats on the surface, drifting with the wind into beds which may become several feet thick. If the temperature drops below the freezing point of the sea water, the mixture of snow and water freezes quickly into a soft ice similar to that formed when snow is not present. As it ages, sea ice becomes harder and more brittle.

Close to land the ice may be attached to the shore as an **ice foot.** The width of this **fast ice** varies considerably, but in an area with many irregularities in the coast line, especially if there are offshore islands or shoals, and relatively shallow water, it may extend for several miles to seaward. Although the width generally varies from two to 20 miles, a maximum of about 270 miles has been observed in the vicinity of Novosibirskiye Ostrova (New Siberian Islands). On an exposed, abrupt coast bordered by deep water there may be no ice foot at all.

In a bay or other sheltered area, ice formed on the surface of the sea, often augmented by snow and land ice, may build up a shelf which remains attached to the land for many years. In the Ross Sea in Antarctica this **shelf ice** attains a thickness of 500 to 1,000 feet. At the outer edge, large pieces eventually break away, forming **tabular icebergs** (fig. 3604a), with dimensions measured in *miles.* In 1854 and 1855 several ships in the South Atlantic reported a crescent-shaped iceberg with one horn 40 miles long, the other 60 miles long, and with an embayment 40 miles wide between the tips. In 1927 a berg 100 miles long, 100 miles wide, and 130 feet high above water was reported. The largest iceberg ever reported was sighted in 1956 by the USS *Glacier*, a U. S. Navy icebreaker, about 150 miles west of Scott Island. This berg was 60 miles wide and 208 miles long, more than twice the size of Connecticut. Icebergs ten miles or more in length have been seen on many occasions in the antarctic. In contrast, the largest iceberg reported in the northern hemisphere was seven miles long and three and a half miles wide. This berg was sighted off Baffin Island in 1882. In 1928 an iceberg four miles long was reported seen in the North Atlantic. The expression "tabular iceberg" is not applied to northern hemisphere bergs, but similar formations there are called **ice islands.** These are believed to originate when shelf ice breaks up north

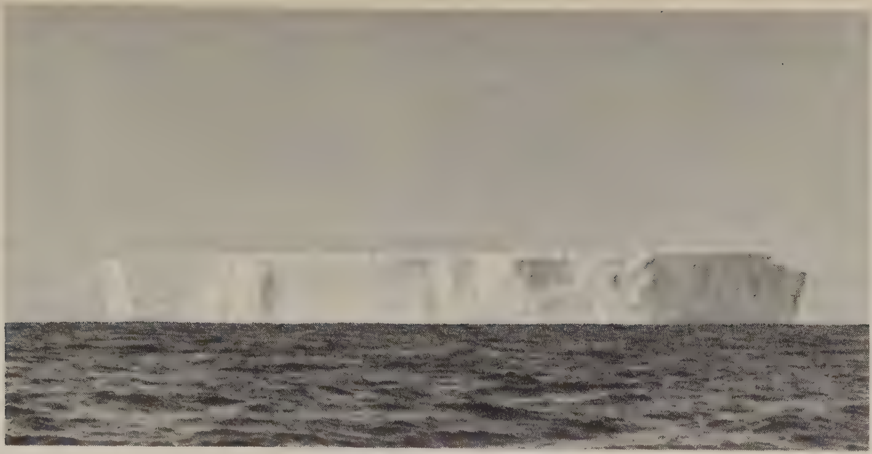

FIGURE 3604a.—A tabular iceberg.

of Canada and Greenland. Most of them remain in the Arctic Ocean and have not been encountered by ships, although the large icebergs sighted in 1882 and 1928 were possibly ice islands. For several years the United States maintained a weather station on one of the arctic ice islands.

Sea ice is exposed to several forces, including currents, wave motion, tides, wind, and temperature differences. In its early stages, its plasticity permits it to conform readily to virtually any shape required by the forces acting upon it. As it becomes older, thicker, and more brittle, exposed sea ice cracks and breaks under the strain. Under the influence of wind and current, the broken pieces may shift position relative to pieces around them.

A single piece of relatively flat sea ice is called an **ice cake.** When ice is formed in the presence of considerable wave motion, circular cakes several feet in diameter are formed, rather than a single large sheet. These circular cakes are called **pancakes,** and a collection of pancakes is called **pancake ice** (fig. 3604b). Wave motion may cause the pancakes to break into smaller pieces. With continued freezing, individual pieces unite into **floes,** and floes into **ice fields** which extend over many miles.

FIGURE 3604b.—Pancake ice, with an iceberg in the background.

When one floe encounters another, or the shore, the individual pieces may be forced closer together into a thickly compacted mass. If the force is sufficient, and the ice is sufficiently plastic, **bending** takes place, or **tenting** if the contacting edges of individual cakes force each other to rise above their surroundings. More frequently, however, **rafting** occurs as one cake overrides another. Sea ice having any readily observed roughness of the surface is called **pressure ice.** A line of ice piled haphazardly along the edge of two floes which have collided is called a **pressure ridge.** Pressure ice with numerous mounds or hillocks which have become somewhat rounded and smooth by weathering or the accumulation of snow is called **hummocked ice,** each mound being called a **hummock.**

The motion of adjacent floes is seldom equal. The rougher the surface, the greater the effect of wind, since each piece extending above the surface acts as a sail. Some floes are in rotary motion as they tend to trim themselves into the wind. Since ridges extend below as well as above the surface, the deeper ones are influenced more by deep-water currents. When a strong wind blows in the same direction for a considerable period, each floe exerts pressure on the next one, and as the distance increases, the pressure becomes tremendous. Near land the result is an almost unbelievably chaotic piling of ice. Individual ridges near the shore may extend as much as 60 or 70 feet above surrounding ice and have a total thickness of 150 to 200 feet in extreme cases. Far from land, the height and thickness seldom exceed half these figures.

The continual motion of various floes results in separation as well as consolidation. A long, narrow, jagged **crack** may appear and widen enough to permit passage of a ship, when it is called a **lead** (lēd). In winter, a thin coating of newly formed ice usually covers the water, but in summer the water remains ice-free until a shift in the movement forces the two sides together again. Before this occurs, lateral motion usually takes place between the floes, so that they no longer fit, and unless the pressure is extreme, numerous patches of open water remain. A large one is called a **polynya.**

A large mass of sea ice, consisting of various floes, pressure ridges, and openings, is called a **pack** (fig. 3604c). In the arctic the main pack extends over the entire Arctic Ocean and for a varying distance outward from it, the limits receding considerably during summer. Each year a large portion of the ice from the Arctic Ocean moves outward between Greenland and Norway, into the North Atlantic, and is replaced by new ice. Relatively little of the pack ice is more than ten years old. The **ice pole,** the approximate center of the arctic pack, is at latitude 83°.5 N, longitude 160° W, north of western Alaska and about 390 miles from the north pole. In the antarctic the pack exists as a relatively narrow strip between the continent of Antarctica and the notoriously stormy seas which hasten the pack's destruction.

The alternate melting and refreezing of the surface of the pack, producing **weathered ice,** combined with the various motions to which the pack is subjected, result in widely varying conditions within the pack itself. The extent to which it can be penetrated by a ship varies from place to place and with changing weather conditions. In some areas the limit of navigable water is abrupt and complete, as at the edge of shelf ice. Such ice is called a **barrier.**

3605. Thickness of sea ice.—The seasonal thickness of fast ice in two harbors of the northern hemisphere is shown in figure 3605, at the latitudes indicated. Pack ice in these latitudes undergoes a similar change. As ice thickens, it provides increased insulation to protect the sea water beneath from the colder air above, and the rate of freezing decreases. Sea ice rarely exceeds six feet in thickness during its first year. In a coastal area where the melting rate is less than the freezing rate, the thickness increases during succeeding winters, being augmented by compacted and frozen snow, until a maximum thickness of about 12 to 15 feet may eventually be reached. These

FIGURE 3604c.—Pack ice.

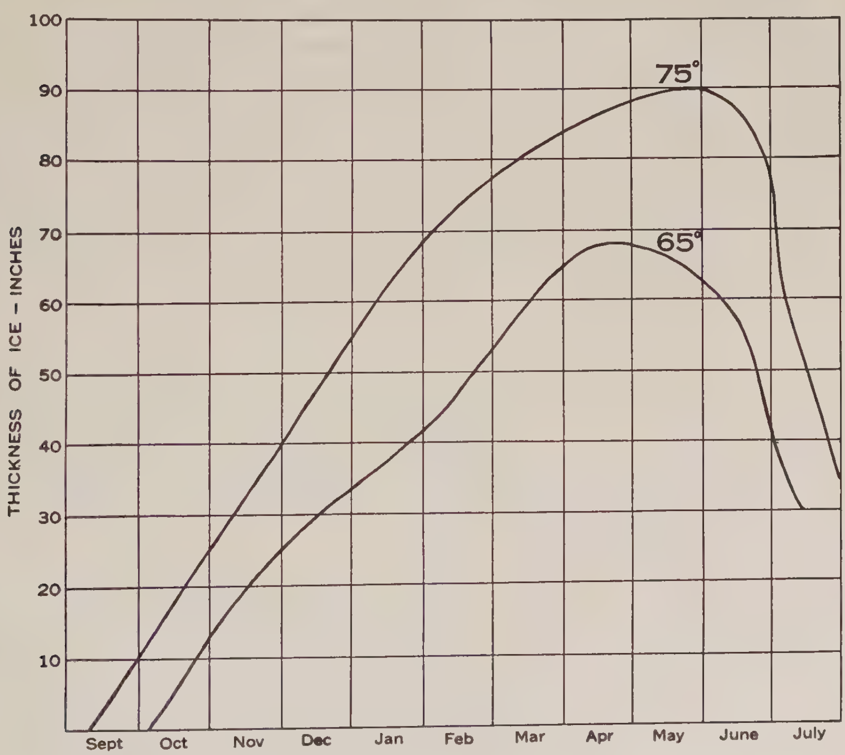

FIGURE 3605.—Thickness of ice in two typical sheltered harbors in the northern hemisphere, at the latitudes indicated.

values refer to single, unbroken pieces of floating ice. Shelf ice and pressure ice may be much thicker, as indicated previously (art. 3604).

During the summer, the sea ice insulates the sea water from warmer air above, so that melting is confined almost entirely to the upper portion. As the fresher melt water runs off into the sea, it tends to float on top of the heavier and colder salt water of the ocean. The temperature of the sea water may be lower than the freezing point of the fresher melt water, resulting in some refreezing as the melt water runs under the ice.

3606. Salinity of sea ice.—Sea ice forms first as salt-free crystals near the surface of the sea. As the process continues, these crystals are joined together and, as they do so, small quantities of brine are trapped within the ice. On the average, new ice six inches thick contains five to ten parts of salt per thousand. With lower temperature, freezing takes place faster. With faster freezing, a greater amount of salt is trapped in the ice.

Depending upon the temperature, the trapped brine may either freeze or remain liquid, but because its density is greater than that of the pure ice, it tends to settle down through the pure ice. As it does so, the ice gradually freshens, becoming clearer, stronger, and more brittle. At an age of one year sea ice is sufficiently fresh that its melt water, if found in **puddles** of sufficient size, and not contaminated by spray from the sea, can be used to replenish the fresh water supply of a ship. However, ponds of sufficient size to water ships are seldom found except in ice of great age, and then much of the melt water is from snow which has accumulated on the surface of the ice. When sea ice reaches an age of about two years, virtually all of the salt has been eliminated. Icebergs contain no salt, and uncontaminated melt water obtained from them is fresh.

The settling out of the brine gives sea ice a honeycomb structure which greatly hastens its disintegration when the temperature rises above freezing. In this state, when it is called **rotten ice,** much more surface is exposed to warm air and water, and the rate of melting is increased. In a day's time, a floe of apparently solid ice several inches thick may disappear completely.

3607. Density of ice.—The density of fresh-water ice at its freezing point is 0.917. Newly formed sea ice, due to its salt content, is more dense, 0.925 being a representative value. The density decreases as the ice freshens (art. 3606). By the time it has shed most of its salt, sea ice is less dense than fresh-water ice, because ice formed in the sea contains more air bubbles. Ice having no salt but containing air to the extent of eight percent by volume (an approximately maximum value for sea ice) has a density of 0.845.

The density of land ice varies over even wider limits. That formed by freezing of fresh water has a density of 0.917, as stated above. Much of the land ice, however, is formed by compacting of snow. This results in the entrapping of relatively large quantities of air. Névé, in the transitional stage between snow and ice, may have an air content of as much as 50 percent by volume. By the time the ice of a glacier reaches the sea, its density approaches that of fresh-water ice. A sample taken from an iceberg on the Grand Banks had a density of 0.899.

When ice floats, part of it is above water and part is below the surface. The percentage of the mass below the surface can be found by dividing the average density of the ice by the density of the water in which it floats. Thus, if an iceberg of density 0.920 floats in water of density 1.028 (corresponding to a salinity of 35 parts per thousand and a temperature of 30° F), 89.5 percent of its mass will be below the surface. That is, about nine-tenths of the mass will be below the surface, and only about one-tenth will be above the surface. If the ice is a perfectly uniform block, which some tabular

icebergs approach, the depth below the surface is about seven times the height above water, under the conditions stated above. However, most of the icebergs of the northern hemisphere are irregular in shape, the depth probably averaging about five times the height. Icebergs have been estimated to be as high as 1,000 feet above water, but the highest measured in the northern hemisphere was 447 feet. The largest tabular icebergs of the antarctic extend about 300 feet above the water.

3608. Drift of ice.—Although surface currents have some effect upon the drift of pack ice, the principal factor is wind. Due to Coriolis force (art. 1611), ice does not drift in the direction of the wind, but about 30° from this direction. In the northern hemisphere, this drift is to the *right* of the direction toward which the wind blows, and in the southern hemisphere it is toward the *left*. Since the surface wind is deflected about twice this amount from the direction of the pressure gradient, the total deflection of the ice is about 90° from the pressure gradient, or along the isobars, with the atmospheric low toward the left and the high toward the right in the northern hemisphere. In the southern hemisphere, these directions are reversed. The *rate* of drift is about one to seven percent of the wind speed, depending upon the roughness of the surface and the concentration of the ice.

Icebergs, which extend a considerable distance below the surface, and have a relatively small "sail area," are influenced more by surface currents than by wind. However, if a strong wind blows for a number of hours in a steady direction, the drift of icebergs will be materially affected. In this case the effect is two-fold. The wind acts directly against the iceberg, and also generates a surface current in about the same direction. Because of inertia, an iceberg may continue to move from the influence of wind for some time after the wind stops or changes direction.

3609. Extent of ice in the sea.—Several Hydrographic Office publications contain monthly charts showing average extent of various degrees of navigability in the northern and southern hemispheres throughout the year. A sample of the type of information given is shown in figure 3609. Similar information is shown on the various pilot charts (art. 414). Useful information on ice conditions in different localities is given in the sailing directions for those areas. The information given in H.O. Pub. No. 27, *Sailing Directions, Antarctica*, is particularly complete and of somewhat general application.

However, since formation of ice, in common with other meteorological and oceanographic phenomena, varies considerably from year to year, wide deviations from average conditions are not unusual. Most countries having vessels operating in ice maintain ice information services. Details of these services are given in the appropriate volumes of sailing directions. The ice bulletins broadcast by the U. S. Navy Hydrographic Office are discussed in article 3615. The latest bulletins, as well as information on average conditions, should be consulted when operating in ice.

3610. Ice in the North Atlantic.—Sea-level glaciers exist on a number of land masses bordering the northern seas, including Alaska, Greenland, Svalbard (Spitzbergen), Zemlya Frantsa-Iosifa (Franz Josef Land), Novaya Zemlya, and Severnaya Zemlya (Nicholas II Land). Except in Greenland, the rate of calving is relatively slow, and the few icebergs produced melt near their points of formation. Many of those produced along the coasts of Greenland, however, are eventually carried into the shipping lanes of the North Atlantic, where they constitute a major menace to ships. It is for this reason that more southerly lanes (art. 3611) are specified when icebergs are prevalent.

The icebergs produced along the east coast of Greenland are carried by the east Greenland current around Kap Farvel and northward by the west Greenland current toward Davis Strait. Relatively few of these icebergs menace shipping, but they have been encountered as far as 200 miles southeast of Kap Farvel.

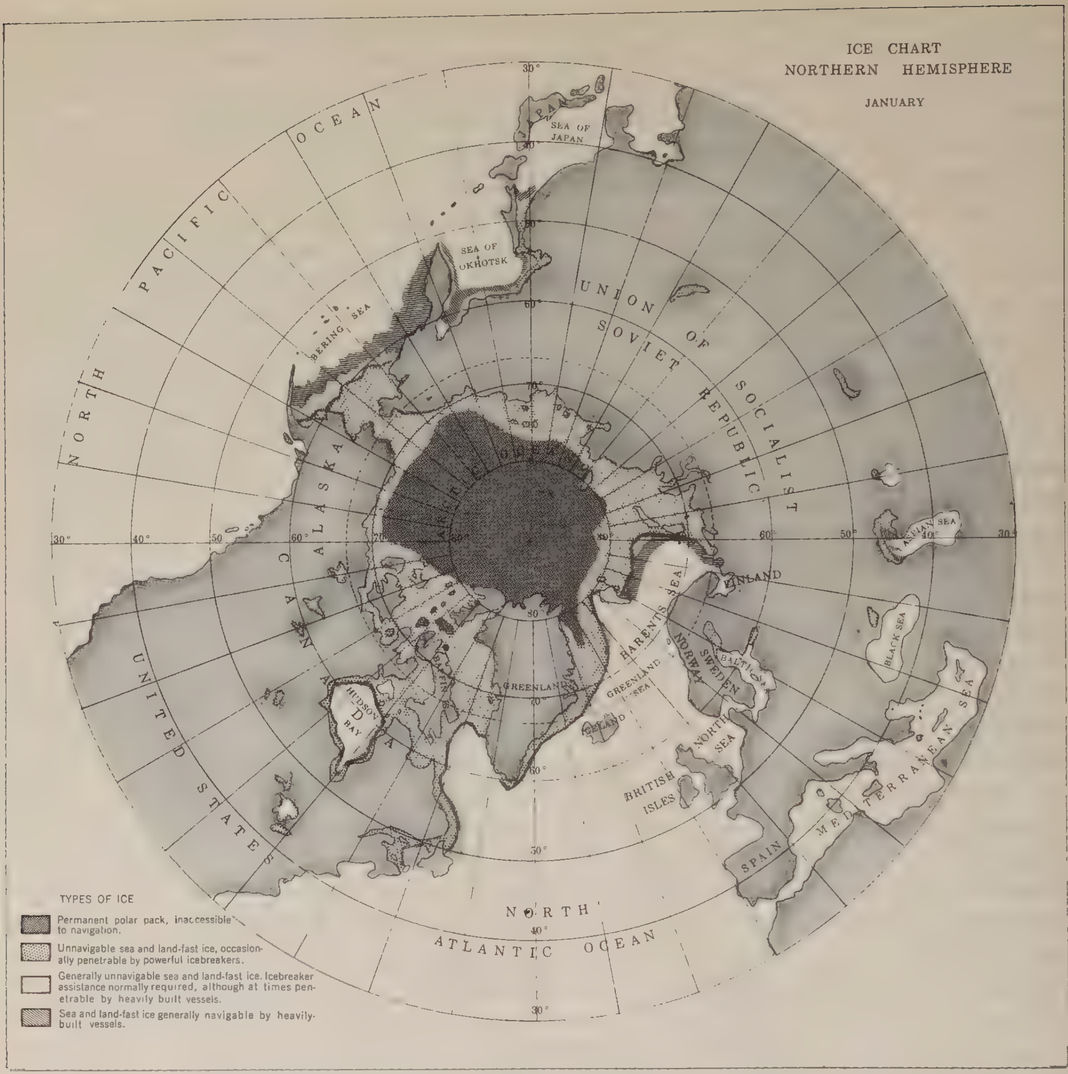

FIGURE 3609.—Average limits of various degrees of navigability of ice in the northern hemisphere in January.

The most prolific source of icebergs is the west coast of Greenland. In this area there are about 100 tidewater glaciers, 20 of them being the principal producers of icebergs. About 7,500 icebergs are formed here each year. The west Greenland current carries them northward and then westward until they encounter the south-flowing Labrador current. West Greenland icebergs generally spend their first winter in Baffin Bay. During the next summer they are carried southward by the Labrador current. In many cases, their second winter is spent in Davis Strait. When they are freed by the break-up of the pack ice, they drift southward. An average of about 400 per year reach latitude 48° N, and about 35 are carried south of the Grand Banks (latitude 43° N) before they melt. Icebergs have been encountered south of Bermuda, off the Azores, and within a few hundred miles of Great Britain.

The variation from average is considerable. More than 1,350 icebergs have been sighted south of latitude 48° N in a single year (1929), while in 1940 only two were encountered in this area. Although this variation has not been fully explained, it is

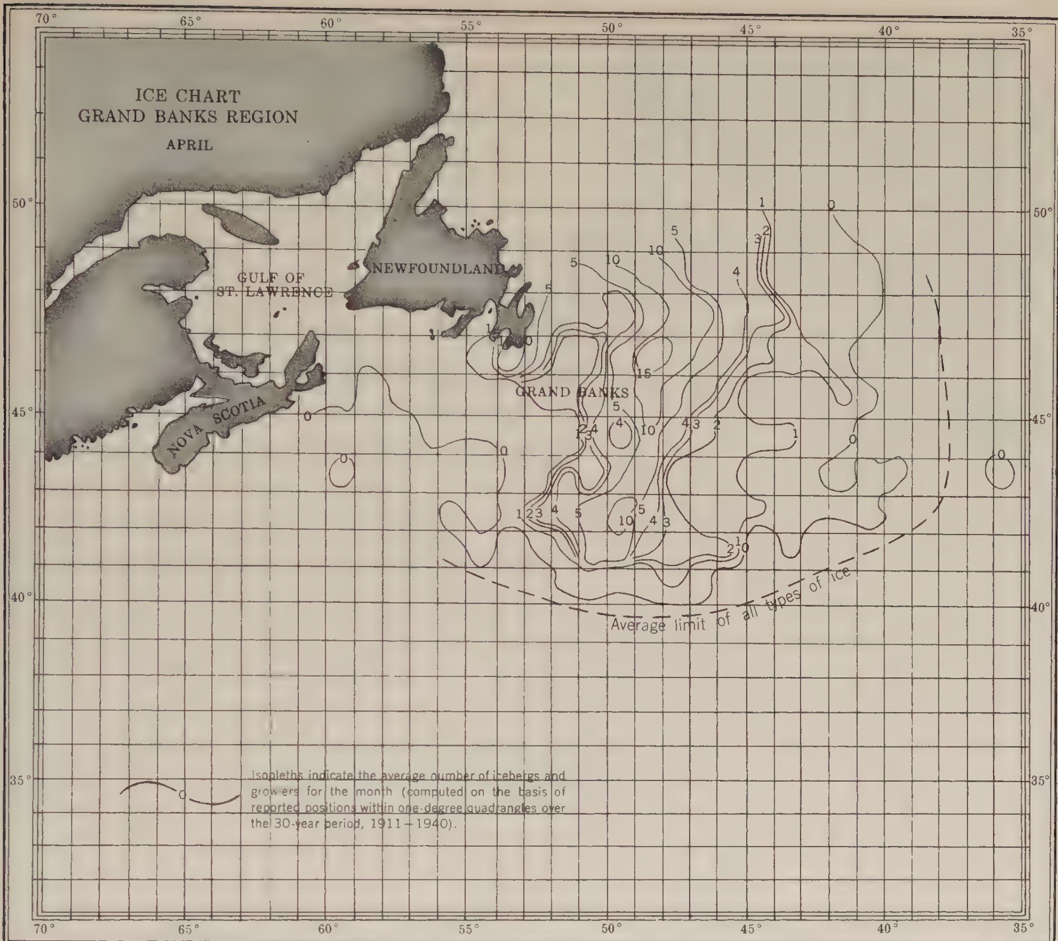

FIGURE 3610a.—Average iceberg conditions in the vicinity of the Grand Banks in April.

apparently related to wind conditions, the distribution of pack ice in Davis Strait, and to the amount of pack ice off Labrador. It has been suggested that the distribution of the Davis Strait-Labrador Sea pack ice influences the effectiveness of this ice in holding back the icebergs. According to this theory, when pack ice is heavy along the Labrador coast, the icebergs are forced well offshore, where warmer water causes them to melt before they reach the North Atlantic shipping lanes; but when the pack ice is not sufficient for this, the icebergs drift closer to shore, where there is colder water which prolongs their existence.

Icebergs may be encountered during any part of the year, but in the Grand Banks area they are most numerous during the spring. Average iceberg and pack ice conditions in this area during April, May, and June are shown in figures 3610a, 3610b, and 3610c. Off Newfoundland, part of the pack ice is brought south by the Labrador current, and part of it comes through Cabot Strait, having originated in the Gulf of St. Lawrence.

3611. The North Atlantic lane routes.—In his 1855 sailing directions, Matthew Fontaine Maury included a section on "Steam Lanes Across the Atlantic." Maury was inspired by the collision and sinking the previous year of the French *Vesta* and American *Arctic*, in which about 300 lives were lost, and he recommended separate

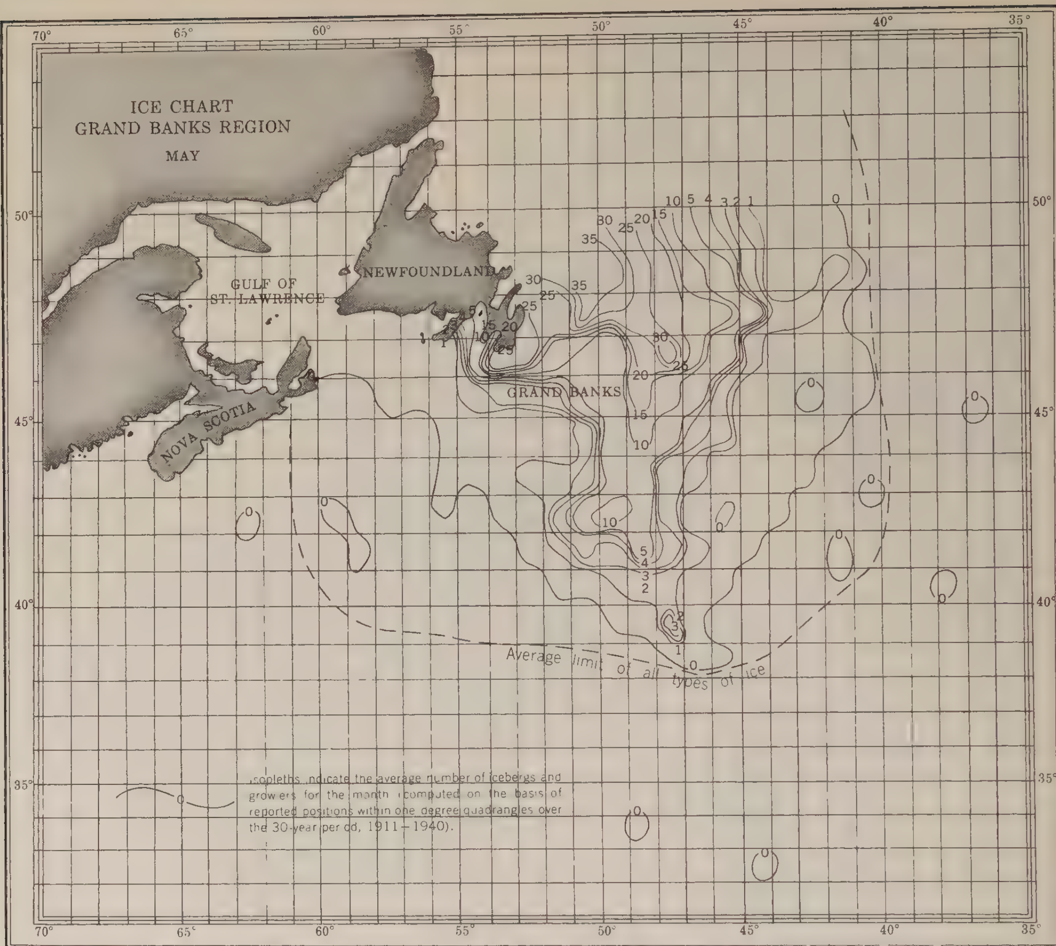

FIGURE 3610b.—Average iceberg conditions in the vicinity of the Grand Banks in May.

routes for eastbound and westbound vessels to avoid the risks due to fog. The U. S. Navy Hydrographic Office continued to advocate the use of lane routes during the next 35 years, ultimately designating different routes for different times of the year to avoid ice dangers. In 1889 representatives of 26 maritime nations, meeting at the International Marine Conference in Washington, ruled against establishing steamer lanes by international agreement of the governments involved, but recommended that companies engaged in the North Atlantic trade establish such routes for their own vessels. Two years later a group of steamship companies operating passenger liners in the North Atlantic, led by the Cunard Line, agreed to follow designated tracks which were essentially the ones proposed by the U. S. Navy Hydrographic Office. The lanes have been altered somewhat from time to time. The principal ones now in use are shown in figure 3611. Each lane is composed of two tracks separated by a safe distance, the southern track being used by eastbound vessels, and the northern one by westbound vessels.

Routes *A*, *B*, and *C* connect the United States and Europe, while routes *D*, *E*, *F*, and *G* run between Canada and Europe. Normally, route *B* is used between April 11 and June 30, and route *C* during the remainder of the year. However, when icebergs are numerous south of the Grand Banks, the use of lane *A* is specified. This route

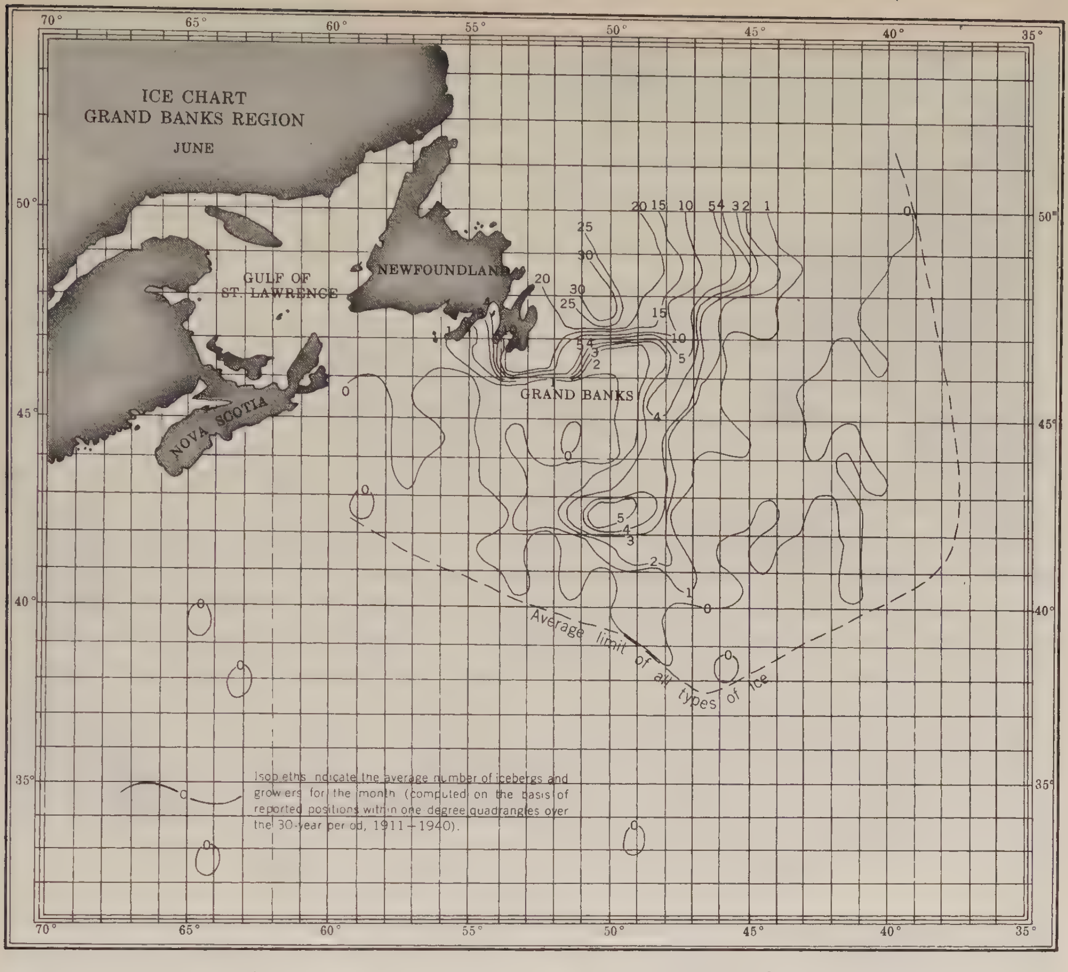

FIGURE 3610c.—Average iceberg conditions in the vicinity of the Grand Banks in June.

adds 150 to 200 miles to the great-circle track, but the increased distance is acceptable because it improves the safety and reduces the possibility of delays due to pack ice. Normally, route *D* is used between February 15 and April 10; route *E* from April 11 through May 15, and from December 1 through February 14; route *F* from May 16 until route *G* is clear, about July 1, or through November 30 if route *G* is not used; and route *G* from the opening of Belle Isle Strait, about July 1, through November 14. Specified lanes are shown on pilot charts for the North Atlantic (H.O. Chart No. 1400).

Variations in this schedule are specified by a designated official of the Cunard Line, acting upon advice from the Hydrographer of the U. S. Navy. The Hydrographer makes his recommendation after consultation with the Commandant of the U. S. Coast Guard, taking into account the information provided by the International Ice Patrol (art. 3612). Virtually all passenger liners and most freight vessels use these routes.

3612. The International Ice Patrol was established in 1913 by the International Convention for the Safety of Life at Sea held that year as a result of the sinking of the SS *Titanic* the previous year. On its maiden voyage this vessel struck an iceberg and sank with the loss of 1,513 lives. In accordance with the agreement reached at the convention, this patrol is conducted by the U. S. Coast Guard, which each year

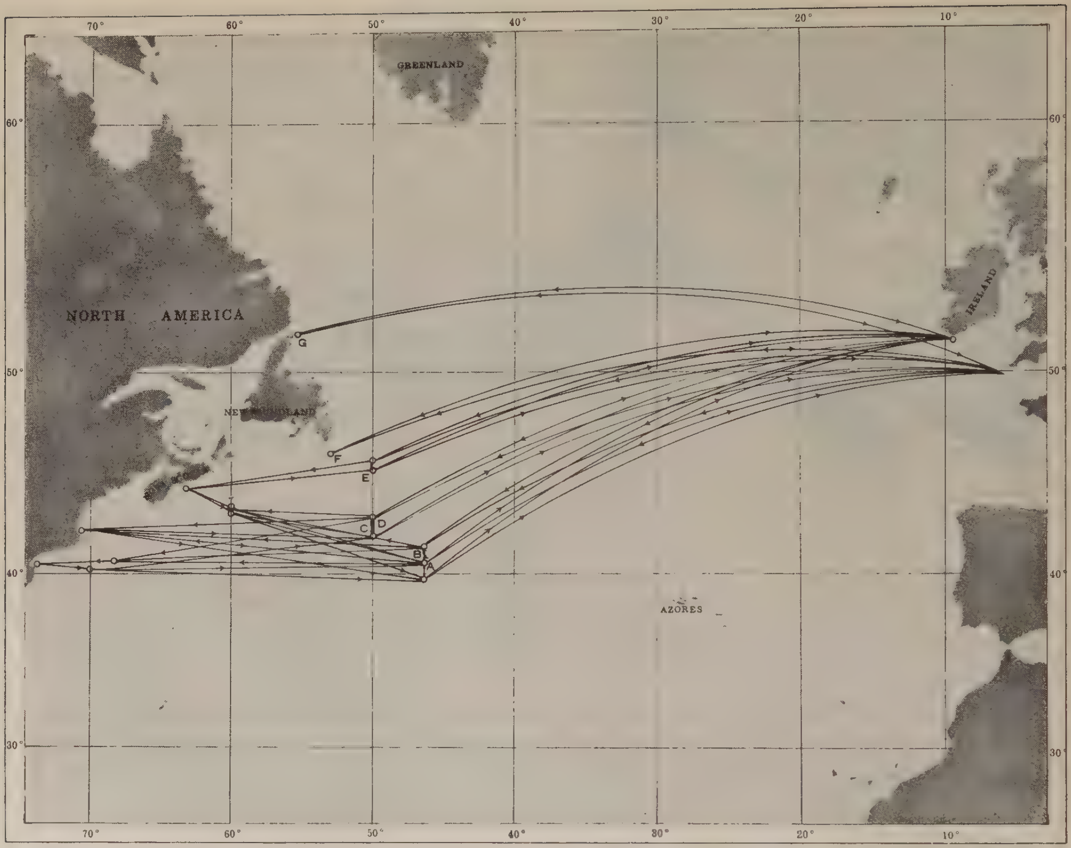

FIGURE 3611.—Principal North Atlantic steamer lanes.

assigns vessels to remain in the vicinity of the Grand Banks during the ice season to observe and report ice conditions.

During the war years of 1916–18 and 1941–45 the patrol was suspended. Following World War II, aircraft were added to the patrol force, and Argentia, Newfoundland, was established as the base of operations. Aircraft have played an increasing role in ice reconnaissance each year since then, and today they perform most of the work. Twice each day during the iceberg season an ice bulletin is broadcast from Argentia and printed in the *Daily Memorandum* of the U. S. Navy Hydrographic Office. Ice patrol vessels copy the broadcasts when on station and make them available to other ships upon request. In return for this service, all vessels in the area are requested to report to the patrol vessels any ice observed, and to send weather data and surface sea water temperature every four hours.

When engaged in patrolling ice areas, the vessels conduct oceanographic surveys and maintain an up-to-date map of the currents, for use in predicting future drift of icebergs. Recommendations for changes in the use of lane routes (art. 3611) are based upon information gathered by the International Ice Patrol.

As used by the U. S. Coast Guard, the expression "ice observation service" means that a continuous surface vessel patrol is *not* in effect, ice reconnaissance being accomplished chiefly by aircraft. When a continuous surface patrol is used to augment the ice observation service, the expression "ice patrol service" is used.

3613. Ice detection.—As a ship proceeds into higher latitudes, the first ice it encounters is likely to be in the form of icebergs, because such large pieces require a longer time to disintegrate. Icebergs can easily be avoided if detected soon enough.

The distance at which an iceberg can be seen depends upon the visibility, height of the berg, source and condition of lighting, and the observer. On a clear day with excellent visibility a large berg might be sighted at a distance of 18 miles. With a low-lying haze around the horizon this may be reduced to ten miles. In light fog or drizzling rain this is further reduced to one to three miles. There is a tendency to over-estimate the distance.

In a dense fog a berg may not be visible until it is close aboard, when it appears as a luminous, white mass if the sun is shining; or as a dark, sombre mass if the sun is not shining. If the layer of fog is not thick, an iceberg may be sighted from aloft sooner than from a point lower in the vessel, but this fact should not be considered justification for omitting a bow lookout.

On a clear, dark night an iceberg will seldom be picked up visually at a distance greater than one-fourth of a mile, but if its bearing is known, an observer with binoculars can occasionally observe a light spot where a wave breaks against it at a distance of a mile.

A moon may either help or hinder, depending upon its phase and position relative to ship and berg. A full moon in the direction of the berg interferes with its detection, while light from one in the opposite direction produces a "blink" which renders the iceberg visible for a greater distance, possibly as much as three miles. Clouds, particularly broken clouds, with intermittent moonlight, add to the difficulty of detecting ice.

If an iceberg is in the process of disintegration, its presence may be detected by the cracking sound as a piece breaks off, or by the thunderous roar as a large piece falls into the water. The appearance of smaller pieces of ice in the water often indicates the presence of an iceberg nearby. In calm weather such pieces may form a curved line with the parent iceberg on the concave side. Some of the pieces broken from an iceberg are themselves large enough to be a menace to ships.

As the ship proceeds to higher latitudes, it eventually encounters pack ice. If the ice is approached from leeward, it is likely to be loose and somewhat scattered, often in long, narrow arms. If it is approached from windward, it is usually compact and the edge is sharply defined.

One of the most reliable signs of the approach to pack ice, especially from leeward, is the somewhat abrupt smoothing of the sea in a fresh breeze, and the more gradual lessening of the swell. Abrupt changes in air or sea temperature or sea-water salinity are not reliable signs of the approach to either icebergs or pack ice, but if the sea temperature gradually drops below 32° F, the ship *may* be nearing an ice field.

Another reliable sign of the approach to pack ice is the appearance of the horizon or sky. A yellowish glare or **ice blink** appears in the sky above an ice field. If clouds are present, the blink is whiter. Reflection of light from snow, whether on land or sea ice, is white and is called **snow blink.** In contrast, the sky above open water is dark. This is called **water sky.** Somewhat similar **land sky** above ice- and snow-free land is grayer. The combination of these various effects in the sky is called a **sky map.** One experienced in reading the sky map finds it very useful in avoiding ice or searching out openings which may permit his vessel to make progress while proceeding through an ice field.

The presence of seals or certain types of birds may indicate the presence of ice nearby. It is well to observe the habits of the various species encountered.

If aircraft or other vessels can be contacted by radio, much useful information can sometimes be obtained from them. Some ships, particularly icebreakers, proceeding into high latitudes carry helicopters, which are invaluable in locating ice and determining the relative navigability of different portions of it.

Echoes from the ship's whistle or horn will sometimes reveal the presence of icebergs, but are useless against pack ice. Such echoes can give an indication of direction, and if the time interval between the sound and its echo is measured, the distance in feet can be determined by multiplying the number of seconds by 550. However, echoes are not a reliable indication because only those pieces of ice with large vertical areas facing the ship return enough echo to be heard, and also because echoes might be received from land or a fog bank.

At relatively short ranges, sonar is sometimes helpful in locating ice. The first contact with icebergs may be when as much as three miles or more off, but is usually considerably less. Growlers may be picked up at one-half to one mile and even smaller pieces may be detected in time to avoid them. Since one-half to seven-eighths of the mass of ice is below the surface, the underwater portion presents a better target than the portion above water.

Radar is highly useful in detecting ice, but is by no means infallible. Ice is a relatively poor radar target, and much depends upon the nature of the exposed surface. Icebergs with sides sloping gently toward the vessel can be seen visually long before they are picked up by radar, if the day is clear. One iceberg 700 feet long and 200 feet high was reported to have been approached to within three miles before it appeared on the radar screen. However, the average berg is picked up at a range of eight to ten miles, and the large vertical-sided tabular icebergs of the antarctic are usually detected at ranges of 15 to 30 miles, with an extreme range of 37 miles having been reported. Growlers are the chief concern. While a large iceberg is almost always detected in time to be avoided, a growler large enough to be a serious menace may be lost in the sea return and escape detection altogether. If an iceberg or growler is detected, tracking is sometimes necessary to distinguish it from a rock, islet, or ship.

Against sea ice, radar can be of great assistance to one experienced in interpreting the scope picture. Smooth sea ice, like smooth water, returns little or no echo, but rough, hummocky sea ice can be detected at a range of two to three miles. The return is similar to sea return, but the same echoes appear at each sweep. A lead in smooth ice broken by a preceding vessel is clearly visible, even though a thin coating of new ice has formed in the opening. A light covering of snow obliterating many of the features to the eye has little effect upon a radar return.

The ranges at which ice can be detected by radar are somewhat dependent upon refraction, which is sometimes quite abnormal in polar regions. Adequate training and experience are essential if full benefit is to be realized from radar.

No method yet devised to detect the presence of ice is infallible, and all should be regarded with suspicion, although none should be overlooked. In ice, as elsewhere, *there is no substitute for constant vigilance.*

3614. Operations in ice.—For operations in ice it is preferable to have a vessel designed for this purpose. Such a vessel has a heavily reinforced bow, reinforced plating along the water line, absence of vertical sides, deep screws, blunt bow, and other desirable features. The full list depends upon the area of operations, kinds of ice to be encountered, length of stay in the vicinity of ice, anticipated assistance by icebreakers, and possibly other factors. Any vessel expecting to penetrate the pack ice should as a minimum have reinforcement along the water line, particularly at the bow, which should be strengthened both inside and outside.

Whatever the nature of the vessel, it will be subjected to various hazards which may cause damage. Its safety depends largely upon the thoroughness of advance preparations, the alertness and skill of its crew, and their ability to make repairs if damage is sustained. Before the ice is entered, the ship should be trimmed so as to be down by the stern slightly (not more than two or three feet).

In the vicinity of icebergs, a sharp lookout should be kept and all bergs given a wide berth. It is dangerous to approach close to them because of the possibility of encountering underwater extensions and because bergs that are disintegrating may suddenly capsize or readjust their masses to new positions of equilibrium. In periods of low visibility the utmost caution is needed. The speed should be reduced and the watch prepared for quick maneuvering.

Upon the approach to pack ice, a careful decision is needed to determine the best action. Often it is possible to go around the ice, rather than through it. Unless the pack is quite loose, this action usually gains rather than loses time. When skirting a field of ice or an iceberg, do so to windward, if a choice is available, to avoid projecting tongues of ice or individual pieces that have been blown away from the main body of ice.

When it is considered necessary to enter pack ice, select the point of entry with great care. Get all available information on the nature and extent of ice and open water. Seek the weakest part of the ice and particularly avoid ice under pressure. If an offshore wind is blowing, a relatively ice-free shore lead may be available. Enter ice from leeward if possible, at slow speed. Enter on a course perpendicular to the ice edge, avoiding projecting tongues of ice.

Having entered the pack, always *work with the ice, not against it*, and *keep moving*, but do not rush the work of negotiating the pack. Patience may pay big dividends. Respect the ice but do not fear it. Stay in open water or areas of weak ice if possible, remembering that it is better to make good progress in the *general* direction desired than to fight heavy floes in the *exact* direction to be made good. However, avoid the temptation to proceed far to one side of the course. It is sometimes better to back out and seek a more penetrable area, being careful not to damage the screws while backing. Keep clear of corners and projecting points of ice. Never hit a large piece of ice if it can be avoided, but if it cannot be avoided, hit it head-on. Keep a sharp watch on the screws and rudder, fending off pieces of ice which might damage these vital parts, or stopping the propellers if the ice cannot be avoided. Back with extreme caution. Aircraft, particularly helicopters, are of great value in determining the nature and distribution of ice ahead. Since ice is continually shifting its position, the changing situation should be kept under observation and all forms of pressure avoided if possible. The windward side of icebergs within pack ice should be avoided because the pack ice usually moves with the wind, while the berg does not do so to the same extent, resulting in pressure on the windward side and open water to leeward. Because of its poor maneuverability in ice, a vessel may even be set down upon the iceberg.

If a narrow strait or a bay is entered, an alert watch should be maintained, because if the wind blows directly into the confined space, drifting ice may be forced down upon the vessel. An increase in wind on the windward side of a prominent point, grounded iceberg, or land ice tongue extending into the sea may similarly endanger a vessel.

While a ship is in pack ice, it is always in danger of being **beset,** or so closely surrounded by ice that steering control is lost. It may then be carried into shallow water or heavy ice with dangerous underwater projections. If pressure is exerted against the hull, the vessel is said to be **nipped.** When this occurs, it is in danger of being crushed. A ship in the ice is in constant danger of colliding with sharp pieces of ice, and while in the ice sharp turns to avoid such collisions may throw the stern against the ice, resulting in a bent or broken screw blade or propeller shaft. If a ship cannot free itself by maneuvering, an explosive charge or ice saws may have to be used. Dynamite is the explosive usually used. If detonated while the engines are going full astern and a strain is taken on an **ice anchor** (a stockless, single-fluked hook imbedded in the ice),

a 2½ pound charge placed in a hole cut nearly to the bottom of the ice about 35–40 feet off the beam may help to free a beset ship.

Attempts to clear ice jams in navigable channels by use of explosives and with the heat generated by thermite charges have met with some success, but the same tactics used against icebergs at sea have proven of little value. Icebergs in the southern Grand Banks area have disintegrated more rapidly when depth charges have been detonated against their underwater portions, but destruction by this method, as well as by other types of ordnance attempted, has been resisted by icebergs in higher latitudes.

If an icebreaker is in the vicinity, its instructions should be followed carefully in all ice operations.

Underice submarine operations require information on the thickness of ice below the surface as well as the extent of water openings between ice floes. While icebergs are believed to extend to depths of nearly 1,000 feet, ice hummocks between floes of polar ice may extend 150 feet below sea level. Submarine navigation thus involves vertical positioning as well as dead reckoning considerations, plus the necessity of finding open water or thin ice for surfacing purposes.

Only the basic principles of operating in ice have been given. Before entering areas of ice, those responsible for the maneuvering of a ship should become well acquainted with the experience of others who have operated in ice, especially those who have been in the same area. Some of this information is to be found in various volumes of sailing directions, particularly those for Antarctica (H.O. Pub. No. 27), and additional information is available at the U.S. Navy Hydrographic Office.

3615. Ice observing and forecasting.—Advance knowledge of ice conditions to be encountered is valuable in both planning and operational phases of any program to be conducted in high latitudes. Through the cooperation of observers aboard ship, in the air, and on land, the U. S. Navy Hydrographic Office collects and analyzes ice data in the arctic, and distributes ice information in the form of ice bulletins as part of regularly scheduled broadcasts.

For this program to be fully effective, it is essential that all vessels and air units operating in ice areas cooperate by submitting reports. To assist in this program, and to provide uniformity in reporting procedure, the U. S. Navy Hydrographic Office has published an observer's manual, H.O. Pub. No. 606–d, *Ice Observations;* H.O. Pub. No. 609, *A Functional Glossary of Ice Terminology;* and convenient ice log forms for recording the observations. When filled in, the log sheets are mailed to the U. S. Navy Hydrographic Office, Washington, D. C., and certain reports are sent by radio. The mariner who regularly sends complete reports can contribute to an increase in knowledge of ice conditions and to the accuracy and completeness of ice bulletins.

In addition to its ice bulletins, the U. S. Navy Hydrographic Office is developing techniques for forecasting ice growth and thickness, movement and concentration, and melting and break-up.

WEATHER

PART SEVEN

WEATHER

CHAPTER XXXVII

WEATHER OBSERVATIONS

3701. Introduction.—Weather forecasts are generally based upon information acquired by observations made at a large number of stations. Ashore, these stations are located so as to provide adequate coverage of the area of interest. Most observations at sea are made by mariners, wherever they happen to be. Since the number of observations at sea is small compared to the number ashore, marine observations are of importance in areas where little or no information is available from other sources. Results of these observations are recorded in the deck log (art. 3726), or other appropriate form. Data recorded by designated vessels are sent by radio to centers ashore, where they are plotted, along with other observations, to provide data for drawing synoptic charts (art. 3827). These charts are used to make forecasts. Complete weather information gathered at sea is mailed to the appropriate meteorological services for use in the preparation of weather atlases and in marine climatological studies.

The analysis of the weather map can be no better than the weather reports used for making the map. A knowledge of weather elements and the instruments used to measure them is therefore of importance to the mariner who hopes to benefit from weather forecasts.

Instruments of various types have been developed to aid in making weather observations. Some have been in use for many years, while others have been developed only recently. Electronic devices have aided materially, but the full impact of electronics upon meteorology has not yet been felt. Several new types of electronic weather instruments are in various stages of development.

3702. Atmospheric pressure measurement.—The sea of air surrounding the earth exerts a pressure of about 14.7 pounds per square inch on the surface of the earth. This **atmospheric pressure,** sometimes called **barometric pressure,** varies from place to place, and at the same place it varies with time.

Atmospheric pressure is one of the basic elements of a meteorological observation. When the pressure at each station is plotted on a synoptic chart, lines of equal atmospheric pressure, called **isobars,** are drawn to indicate the areas of high and low pressure and their centers. These are useful in making weather predictions, because certain types of weather are characteristic of each type area, and often the wind patterns over large areas are deduced from the isobars.

Atmospheric pressure is measured by means of a **barometer.** A **mercurial barometer** does this by balancing the weight of a column of air against that of a column of mercury. The **aneroid barometer** has a partly evacuated, thin-metal cell which is compressed by atmospheric pressure, the amount of the compression being related to the pressure.

Early mercurial barometers were calibrated to indicate the height, usually in inches or millimeters, of the column of mercury needed to balance the column of air above the point of measurement. While the units **inches of mercury** and **millimeters of mercury** are still widely used, many modern barometers are calibrated to indicate the centimeter-gram-second unit of pressure, the **millibar,** which is equal to 1,000 dynes per square centimeter. A **dyne** is the force required to accelerate a mass of one gram at the rate of one centimeter per second per second. A reading in any of the three units

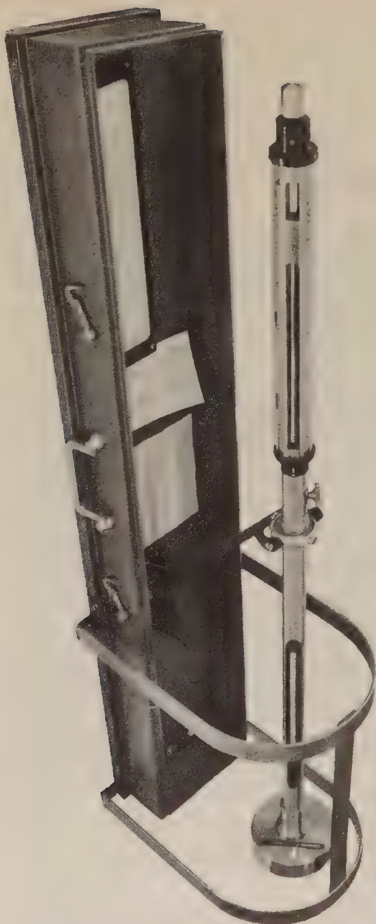

FIGURE 3703.—A shipboard-type mercurial barometer.

of measurement can be converted to the equivalent reading in either of the other units by means of table 14, or the conversion factors given in appendix D.

3703. The mercurial barometer was invented by Evangelista Torricelli in 1643. In its simplest form it consists of a glass tube a little more than 30 inches in length and of uniform internal diameter; one end being closed, the tube is filled with mercury, and inverted into a cup of mercury. The mercury in the tube falls until the column is just supported by the pressure of the atmosphere on the open cup, leaving a vacuum at the upper end of the tube. The height of the column indicates atmospheric pressure, greater pressures supporting higher columns of mercury. A shipboard type is shown in figure 3703.

The mercurial barometer is subject to rapid variations in height, called **pumping,** due to pitch and roll of the vessel and temporary changes in atmospheric pressure in the vicinity of the barometer. Because of this, the care required in the reading of the instrument, its bulkiness, and its vulnerability to physical damage, the mercurial barometer has been largely replaced at sea by the aneroid barometer.

3704. The aneroid barometer (fig. 3704) measures atmospheric pressure by means of the force exerted by the pressure on a partly evacuated, thin-metal element called a **sylphon cell.** A small spring is used, either internally or externally, to partly counteract the tendency of the atmospheric pressure to crush the cell. Atmospheric pressure is indicated directly by a scale and a pointer connected to the cell by a combination of levers. The linkage provides considerable magnification of the slight motion of the cell, to permit readings to higher precision than could be obtained without it.

An aneroid barometer should be mounted permanently. Prior to installation, the barometer should be carefully set to station pressure (art. 3706). An adjustment screw is provided for this purpose. The error in the reading of the instrument is determined by comparsion with a mercurial barometer or a standard precision aneroid barometer. If a qualified meteorologist is not available to make this adjustment, it is good practice to remove only one-half the apparent error. The case should then be tapped gently to assist the linkage to adjust itself, and the process repeated. If the remaining error is not more than half a millibar (0.015 inch), no attempt should be made to remove it by further adjustment. Instead, a correction should be applied to the readings. The accuracy of this correction should be checked from time to time.

A **precision aneroid barometer** used at weather stations ashore, and for comparison of shipboard instruments, is constructed and tested to more exacting tolerances than the ordinary barometer, and provides readings to greater accuracy.

3705. The barograph (fig. 3705) is a recording barometer. Basically, it is the same as a nonrecording aneroid barometer except that the pointer carries a pen at its

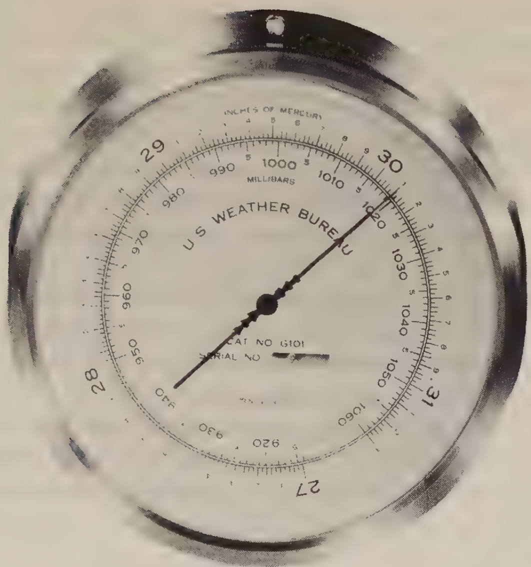

FIGURE 3704.—An aneroid barometer.

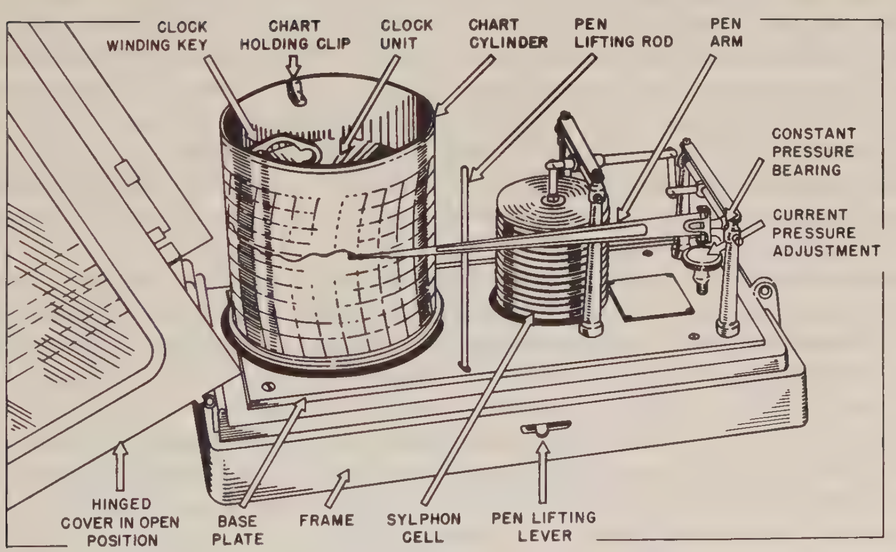

FIGURE 3705.—A barograph.

outer end, and the scale is replaced by a slowly rotating cylinder around which a prepared chart is wrapped. A clock mechanism inside the cylinder rotates the cylinder so that a continuous line is traced on the chart to indicate the pressure at any time.

A **microbarograph** is a precise barograph with greater magnification of deformations due to pressure changes, and a correspondingly expanded chart. Two sylphon cells are used, one being mounted over the other in tandem. Minor fluctuations due to shocks or vibrations are eliminated by damping. Since oil-filled dashpots are used for this purpose, the instrument should not be inverted.

The barograph is usually mounted on a shelf or desk in a room open to the atmosphere, and in a location which minimizes the effect of the ship's vibration. Shock-absorbing material such as sponge rubber is placed under the instrument to minimize the transmission of shocks.

The pen should be checked and the inkwell filled each time the chart is changed, every week in the case of the barograph, and each four days in the case of the microbarograph. The dashpots of the microbarograph should be kept filled with dashpot oil to within three-eighths inch of the top.

Both instruments require checking from time to time to insure correct indication of pressure. The position of the pen is adjusted by a small knob provided for this purpose. The adjustment should be made in stages, eliminating half the apparent error, tapping the case to insure linkage adjustment to the new setting, and then repeating the process.

3706. Adjustment of barometer readings.—Atmospheric pressure as indicated by a barometer or barograph may be subject to several errors, as follows:

Instrument error. Any inaccuracy due to imperfection or incorrect adjustment of the instrument can be determined by comparison with a standard instrument. The U. S. Weather Bureau provides a comparison service. In certain ports a representative brings a standard barometer on board ships which participate in the cooperative observation program of that Bureau. If a barometer is taken to the Weather Bureau, comparison can be made there. The correct sea-level pressure can be obtained by telephone. The shipboard barometer should be corrected for height, as explained below, before comparison with this telephoned value. If there is reason to believe that the barometer is in error, it should be compared with a standard, and if an error is found, the barometer should be adjusted to the correct reading, or a correction applied to all readings.

Height error. Since atmospheric pressure is caused by the weight of air above the place, the pressure decreases as height increases. The correct value at the barometer is called **station pressure.** Isobars adequately reflect wind conditions and geographic distribution of pressure only when they are drawn for pressure at constant height (or the varying height at which a constant pressure exists). On synoptic charts it is customary to show the equivalent pressure at sea level, called **sea level pressure.** This is found by applying a correction to station pressure. The correction, given in table 11, depends upon the height of the barometer and the average temperature of the air between this height and the surface. The outside air temperature taken aboard ship is sufficiently accurate for this purpose. *This is an important correction which should be applied to all readings of any type barometer.*

Gravity error. Mercurial barometers are calibrated for standard sea-level gravity at latitude 45°32′40″. If the gravity differs from this amount, an error is introduced. The correction to be applied to readings at various latitudes is given in table 12. *This correction does not apply to readings of an aneroid barometer.* Gravity also changes with height above sea level, but the effect is negligible for the first few hundred feet, and so is not needed for readings taken aboard ship.

Temperature error. Barometers are calibrated at a standard temperature of 32° F. The liquid of a mercurial barometer expands as the temperature of the mercury rises, and contracts as it decreases. The correction to adjust the reading of the instrument to the true value is given in table 13. *This correction is to be applied to readings of mercurial barometers only.* Modern aneroid barometers are compensated for temperature changes by the use of different metals having unequal coefficients of linear expansion.

3707. Determination of height by barometer.—Since atmospheric pressure is related to height, a barometer can be used to determine height. This is the principle of the **barometric altimeter** commonly used in aircraft.

Ordinary barometers can be used for determination of height *difference,* a problem which often arises in surveying. Simultaneous pressure and temperature readings should be made at both places (heights), if practicable. If this cannot be done, and more than a few minutes will elapse between readings, better values can be obtained by making a reading at the first height, then at the second, and then returning and making another reading at the first station, with approximately equal time intervals between readings. The average of the two readings at the first station is used. All appropriate corrections should be applied except that for height. If P_1 and P_2 are the atmospheric pressures at the two heights, the difference in height can be computed by Babinet's formula:

$$\text{Diff. in height} = C \times \frac{P_1 \sim P_2}{P_1 + P_2}.$$

If T_1 and T_2 are the air temperatures at the two places in degrees Fahrenheit, and difference in height is in feet,

$$C = 52{,}494\left(1 + \frac{T_1 + T_2 - 64}{900}\right).$$

If temperature is in degrees Celsius (centigrade), and difference in height is in meters,

$$C = 16{,}000\left[1 + \frac{2(T_1 + T_2)}{1000}\right].$$

For differences of not more than a few hundred feet, approximate results can be obtained by dividing the pressure difference in inches by 0.0011 inch, to obtain the answer in feet. This is almost the same as multiplying the pressure difference in hundredths of an inch by nine. For large differences, Babinet's formula is not strictly accurate, although the results should meet most requirements.

3708. Wind measurement consists of determination of the direction *from* which the wind is blowing, and the speed of the wind. Wind direction is measured by a **wind vane,** and wind speed by an **anemometer.**

A wind vane consists of a device pivoted on a vertical shaft, with more surface area on one side of the pivot than on the other, so that the wind exerts more force on one side, causing the smaller end to point into the wind. An indicator may be connected to the shaft to provide continuous measurement of wind direction.

In its simplest form, an anemometer consists of a number of cups mounted on short horizontal arms attached to a longer vertical shaft which rotates as the wind blows against the cups. The speed at which the shaft rotates is directly proportional to the wind speed. The number of rotations may be indicated by a counter or by marks on a revolving drum, or the speed may be indicated directly by a device similar to an automobile speedometer. Still another method is to connect a buzzer or flashing light so calibrated that the number of signals per unit time is the speed in knots or miles per hour.

The standard anemometer used aboard ship has three cups. Some anemometers have four cups, and certain naval vessels use a type called the **bridled cup anemometer,** which has a large number of cups mounted on a shaft which does not rotate freely. An anemometer which uses a propeller as the rotor to measure wind speed, and has a streamlined, tail-type vane to indicate direction, is being installed on some ships. Similar equipment is used ashore, customarily mounted on a guyed mast 13 feet high. Wind direction is transmitted to an indicator or recorder by a synchronous motor, while wind speed is transmitted as a voltage generated by a direct-current magneto driven by the propeller. A synchro system is connected to some wind-measuring equipment to provide remote indication of the velocity (both direction and speed). Lightweight, portable, hand-held instruments for measuring and indicating wind speed in knots are used on some ships, principally aircraft carriers.

Several types of wind speed and direction **recorders** are available. Each instrument is normally supplied with a description and complete operating instructions.

If no anemometer is available, wind speed can be estimated by its effect upon the sea and objects in its path, as explained in article 3710.

Measurement of winds aloft is discussed in articles 3717–3722.

3709. True and apparent wind.—An observer aboard a vessel proceeding through still air experiences an **apparent wind** which is from dead ahead and has an apparent speed equal to the speed of the vessel. Thus, if the actual or **true wind** is zero and the speed of the vessel is ten knots, the apparent wind is from dead ahead at ten knots. If the true wind is from dead ahead at 15 knots, and the speed of the vessel is ten knots, the apparent wind is $15+10=25$ knots from dead ahead. If the vessel makes a 180° turn, the apparent wind is $15-10=5$ knots from dead astern.

In any case, the apparent wind is the vector sum (art. O18) of the true wind and the *reciprocal* of the vessel's course and speed vector. Since wind vanes and anemometers measure *apparent* wind, the usual problem aboard a vessel equipped with an anemometer is to convert this to true wind. There are several ways of doing this. Perhaps the simplest is by the graphical solution illustrated in the following example:

Example 1.—A ship is proceeding on course 150° at a speed of 17 knots. The apparent wind is from 40° off the starboard bow, speed 15 knots.

Required.—The relative direction, true direction, and speed of the true wind.

Solution (fig. 3709a).—Starting at the center of a maneuvering board (art. 1212) or other suitable form, draw a line in the relative direction *from* which the apparent wind is blowing. Locate point 1 on this line, at a distance from the center equal to the speed of the apparent wind (2:1 scale is used in figure 3709a). From point 1, draw a line vertically *downward.* Locate point 2 on this line at a distance from point 1 equal to the speed of the vessel in knots, to the same scale as the first line. The relative direction of the true wind is *from* point 2 (120°) toward the center, and the speed of the true wind is the distance of point 2 from the center, to the same scale used previously (11 kn.). The true direction of the wind is the relative direction plus the true heading, or $120°+150°=270°$.

Answers.—True wind from 120° relative, 270° true, at 11 knots.

A quick solution can be made without an actual plot, in the following manner: On a maneuvering board (H.O. 2665–10), label the circles 5, 10, 15, 20, etc., from the center, and draw vertical lines tangent to these circles. Cut out the 5:1 scale and discard that part having graduations greater than the maximum speed of the vessel. Keep this equipment for all solutions. (For durability, the two parts can be mounted on cardboard or other suitable material.) To find true wind, spot in point 1 by eye. Place the zero of the 5:1 scale on this point and align the scale (inverted) by means of the vertical lines. Locate point 2 at the speed of the vessel as indicated on the 5:1

FIGURE 3709a.—Finding true wind by maneuvering board.

scale. It is always vertically *below* point 1. Read the relative direction and the speed of the true wind using eye interpolation if needed. The U.S. Weather Bureau distributes a wind vector computer called a *Shipboard Wind Plotter* (fig. 3709b). Solution by means of this plotter is illustrated in the following example:

Example 2.—A ship is proceeding on course 270° at a speed of 14.5 knots. The apparent wind is from 40° off the starboard bow, speed 20 knots.

Required.—The relative direction, true direction, and speed of the true wind by U.S. Weather Bureau Shipboard Wind Plotter.

Solution (fig. 3709b).—The true direction of the apparent wind is determined by adding the apparent wind direction to the ship's heading if the wind is from off the starboard bow and subtracting the apparent wind direction if the wind is from off the port bow. In this example, the true direction of the apparent wind is 310°. In this solution the red arrowhead is considered the top of the plotter. Set ship's course, 270°, to the top of the plotter by rotating the protractor disk to set 270° at the red arrow. Using a convenient linear scale, measure vertically downward from the center peg of the

plotting board a distance equivalent to 14.5 knots. Mark this point "S" for ship. Rotate the protractor disk of the plotting board until 310° is at the red arrowhead at the top of the plotting board. Using the same linear scale as for ship's speed, plot vertically downward from the center peg of the plotting board a distance equivalent to 20 knots. Mark this point "W". Rotate the protractor disk until the "S" is vertically above the "W", using the vertical lines on the plotting board to line up the two points. Read the true wind direction at the top of the plotting board. The distance between points "S" and "W" is the true wind speed, using the same scale as in plotting points "S" and "W".

Answers.—True wind direction is 357°, true wind speed is 13 knots.

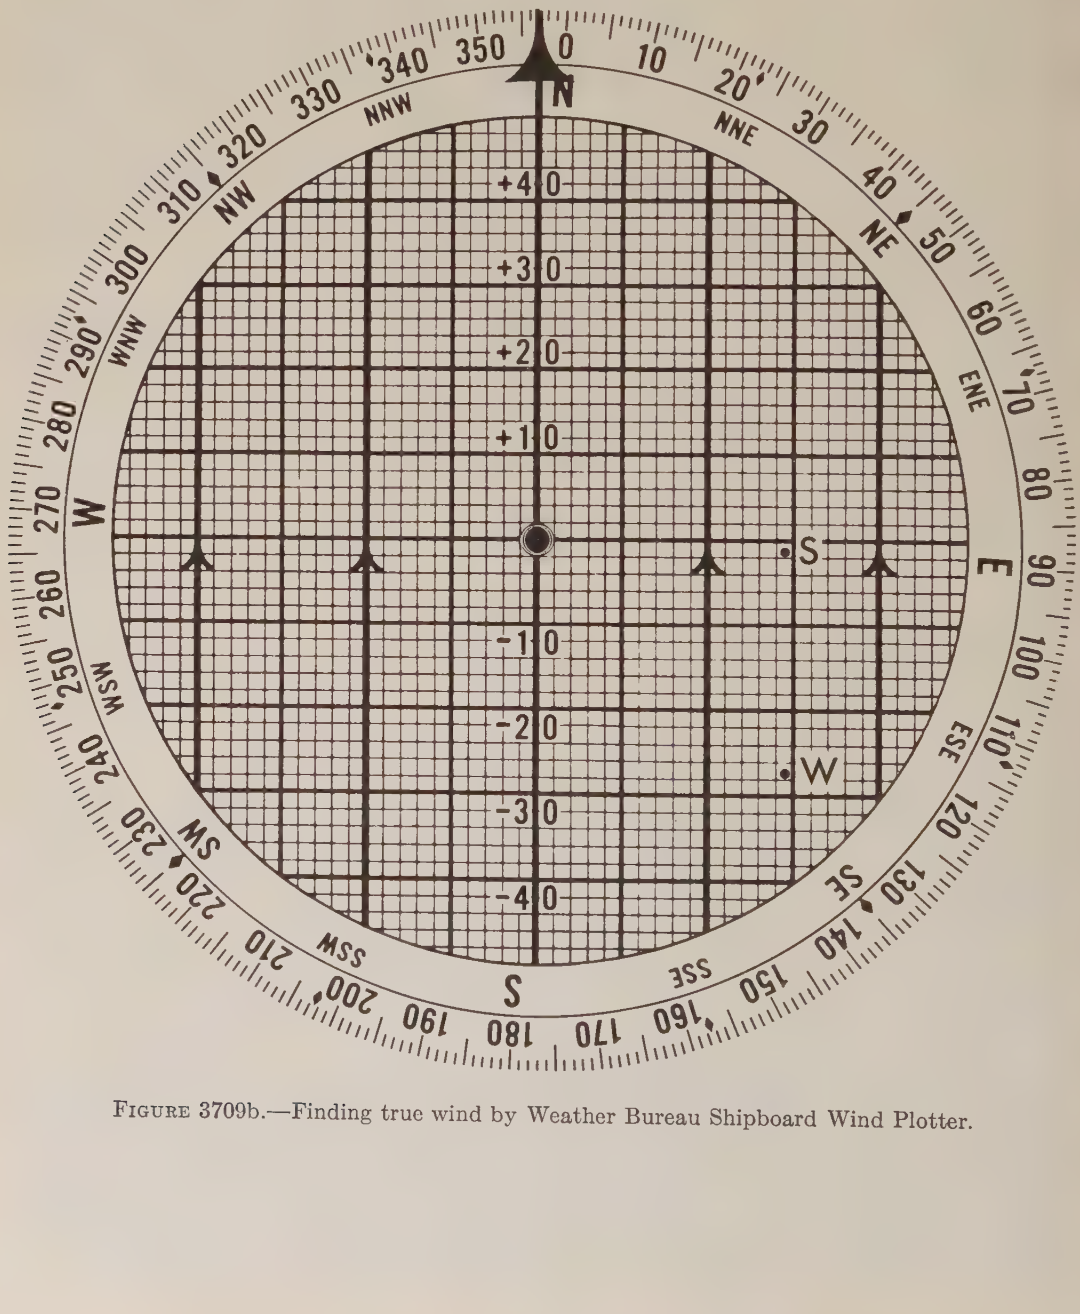

FIGURE 3709b.—Finding true wind by Weather Bureau Shipboard Wind Plotter.

Such problems can be solved by the use of true directions and a regular vector solution, but the use of relative directions simplifies the plot because that component of the apparent wind due to the vessel's motion is always parallel (but reversed) to the vessel's motion, and the apparent wind is always *forward* of the true wind.

A tabular solution based upon the same principle can be made by means of table 10. The entering values for this table are the apparent wind speed *in units of ship's speed,* and the difference between the heading and the apparent wind direction. The values taken from the table are the relative direction (right or left) of the true wind, and the speed of the true wind *in units of ship's speed.* If a vessel is proceeding at 12 knots, six knots constitutes one-half (0.5) unit, 12 knots one unit, 18 knots 1.5 units, 24 knots two units, etc.

Example 3.—A ship is proceeding on course 270° at a speed of ten knots. The apparent wind is from 10° off the port bow, speed 30 knots.

Required.—The relative direction, true direction, and speed of the true wind by table 10.

Solution.—The apparent wind speed is $\frac{30}{10}=3.0$ ship's speed units. Enter table 10 with 3.0 and 10° and find the relative direction of the true wind to be 15° off the port bow (345° relative), and the speed to be 2.02 times the ship's speed, or $2.02\times10=20$ knots, approximately. The true direction is $345°+270°=255°$.

Answers.—True wind from 345° relative, 255° true, at 20 knots.

By variations of this problem, one can find the apparent wind from the true wind, the course or speed required to produce an apparent wind from a given direction or speed, or the course and speed to produce an apparent wind of a given speed from a given direction. Such problems arise in aircraft carrier operations.

Wind speed determined by appearance of the sea (art. 3710) is the speed of the true wind. The sea also provides an indication of the direction of the true wind, because waves move in the same direction as the generating wind, not being deflected by earth rotation (art. 3302). If a wind vane is used, the direction of the apparent wind thus determined can be used with the speed of the true wind to determine the direction of the true wind by vector diagram. If a maneuvering board is used, draw a circle about the center equal to the speed of the true wind. From the center, plot the ship's vector (true course and speed). From the end of this vector draw a line in the direction in which the apparent wind is blowing (reciprocal of the direction from which it is blowing) until it intersects the speed circle. This line is the apparent wind vector, its length denotes the speed. A line from the center of the board to the end of the apparent wind vector is the true wind vector. The reciprocal of this vector is the direction from which the true wind is blowing. If the true wind speed is less than the speed of the vessel, two solutions are possible. If solution is by table 10, the true speed, in units of ship's speed, is found in the column for the direction of the apparent wind. The number to the left is the relative direction of the true wind. The number on the same line in the side columns is the speed of the apparent wind in units of ship's speed. Again, two solutions are possible if true wind speed is less than ship's speed.

3710. Wind and the sea.—The action of the wind in creating ocean currents and waves is discussed in chapters XXXII and XXXIII, respectively. There is a relationship between the speed of the wind and the state of the sea in the immediate vicinity of the wind. This is useful in predicting the sea conditions to be anticipated when future wind speed forecasts are available. It can also be used to estimate the speed of the wind, which may be desirable when an anemometer is not available.

Wind speeds are usually grouped in accordance with the **Beaufort scale** named after Admiral Sir Francis Beaufort, who devised it in 1806. As adopted in 1838, Beaufort numbers ranged from 0, calm, to 12, hurricane. They have now been extended to 17. The Beaufort scale, with certain other pertinent information, is given in appendix R. The appearance of the sea at different Beaufort scale numbers from 0 through 12 is shown in figures 3710a through 3710m.

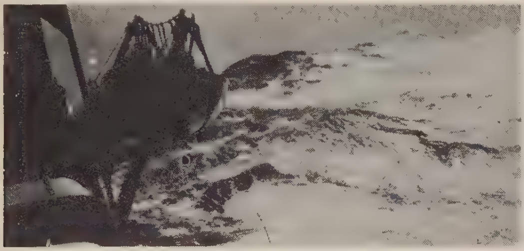

FIGURE 3710m.—Beaufort scale 12.

3711. Temperature is the intensity or degree of heat. It is measured in degrees. Several different temperature scales are in use.

On the **Fahrenheit** (**F**) scale commonly used in the United States and other English-speaking countries, pure water freezes at 32° and boils at 212°.

On the **Celsius** (**C**) scale commonly used with the metric system, the freezing point of pure water is 0° and the boiling point is 100°. This scale has been known by various names in different countries. In the United States it was formerly called the **centigrade** scale. The Ninth General Conference of Weights and Measures, held in France in 1948, adopted the name Celsius to be consistent with the naming of other temperature scales after their inventors, and to avoid the use of different names in different countries. On the original Celsius scale, invented in 1742 by a Swedish astronomer named Anders Celsius, the numbering was the reverse of the modern scale, 0° representing the boiling point of water, and 100° its freezing point.

Réaumur temperature is based upon a scale in which water freezes at 0° and boils at 80°.

Absolute zero is considered to be the lowest possible temperature, at which there is no molecular motion and a body has no heat. For some purposes, it is convenient to express temperature by a scale at which 0° is absolute zero. This is called **absolute**

temperature. If Fahrenheit degrees are used, it may be called **Rankine (R)** temperature; and if Celsius, **Kelvin (K)** temperature. The Kelvin scale is more widely used than the Rankine. Absolute zero is at (−) 459°67 F or (−) 273°15 C.

Temperature by one scale can be converted to that at another by means of the relationship that exists between the scales. Thus,

$$C=\frac{5}{9}(F-32)$$

and

$$F=\frac{9}{5}C+32.$$

A temperature of (−) 40° is the same by either the Celsius or Fahrenheit scale. Similar formulas can be made for conversion of other temperature scale readings. Table 15 gives the equivalent values of Fahrenheit, Celsius, and Kelvin temperatures.

The intensity or degree of heat (temperature) should not be confused with the *amount* of heat. If the temperature of air or some other substance is to be increased (the substance made hotter) by a given number of degrees, the amount of heat that must be added is dependent upon the amount of the substance to be heated. Also, equal amounts of different substances require the addition of unequal amounts of heat to effect equal increase in temperature because of their difference of specific heat (art. 3012). Units used for measurement of amount of heat are the **British thermal unit (BTU)**, the amount of heat needed to raise the temperature of one pound of water one degree Fahrenheit; and the **calorie**, the amount of heat needed to raise the temperature of one gram of water one degree Celsius.

3712. Temperature measurement is made by means of a **thermometer.** Most thermometers are based upon the principle that materials expand with increase of temperature, and contract as temperature decreases. In its most usual form (fig. 3712a) a thermometer consists of a bulb filled with mercury and connected to a tube of very small cross-sectional area. The mercury only partly fills the tube. In the remainder is a vacuum created during construction of the instrument. The air is driven out by boiling the mercury, and the top of the tube is then sealed by a flame. As the mercury expands or contracts with changing temperature, the length of the mercury column in the tube changes. Temperature is indicated by the position of the top of the column of mercury with respect to a scale etched on the glass tube or placed on the thermometer support.

A **maximum thermometer** has a constriction in the tube, near the bulb. As temperature increases, the expanding mercury is forced past the constriction, but will not return as temperature decreases. Thus, it indicates the highest temperature which has occurred since the last setting. This principle is utilized in clinical thermometers, used for measuring body temperature. The mercury can be forced back into the bulb by centrifugal force applied by swinging the arm rapidly. Meteorologists have a device called a "Townsend support" for accomplishing this with less effort and less possibility of breakage.

A **minimum thermometer** (fig. 3712b) uses alcohol instead of mercury. The upper part of the tube contains air under slight pressure, to prevent evaporation of the alcohol with resultant "breaks" in the column as the alcohol later condenses. The thermometer contains an index which is so constructed as to allow alcohol to flow past it up the tube with rising temperatures, but which moves downward in the tube if the temperature falls below it, being drawn down by the effect of surface tension exerted by the bottom of the meniscus (curved upper surface) of the column of alcohol as it reaches the index. Due to this effect, the index remains at the lowest temperature

Figure 3712a.—A thermometer for measuring air temperature.

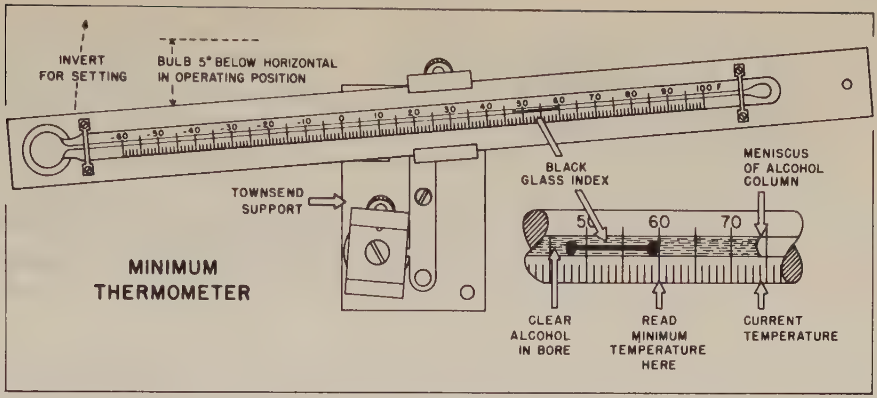

Figure 3712b.—A minimum thermometer.

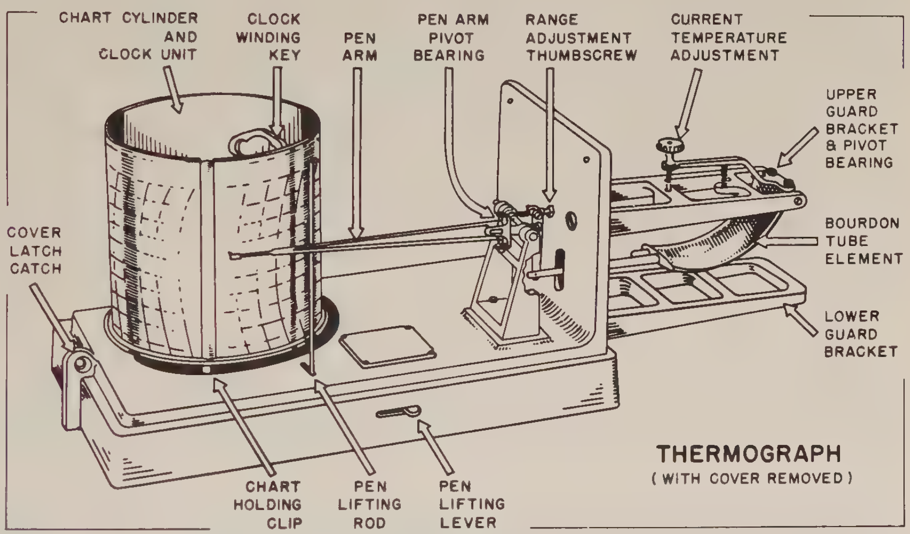

Figure 3712c.—A thermograph with cover removed.

which has occurred since the last setting. Setting is accomplished by tilting the thermometer until the bulb is uppermost, when the index returns to the current temperature. The thermometer is normally maintained at an angle of about 5° to the horizontal, with the bulb at the lower end. A Townsend support is used for this purpose.

Temperature can be measured by means of a **thermograph** (fig. 3712c), which is a recording thermometer. In its outward appearance this instrument is similar to a barograph (fig. 3705). The pen arm is connected, through a linkage, to the thermometric element, which usually consists of a metal tube shaped in the form of an arc and containing alcohol. As the alcohol expands with temperature increase, it tends to straighten the tube; and as the temperature decreases, the contracting alcohol permits the tube to resume its curved shape. The linkage magnifies these variations and transmits them to the pen, which records the temperature on a chart placed around a clock-driven, revolving cylinder.

The freezing point of mercury is about (−) 38° F. Various substances are used to measure lower temperatures, the most common being some form of alcohol, which has a freezing point well below (−) 100° F. For even lower temperatures, below those

ever recorded in the atmosphere, gas may be used instead of a liquid. Thermometers based upon other principles, such as unequal expansion of dissimilar metals, melting point of a substance, color, etc., are sometimes used, particularly for temperatures considerably higher or much lower than those occurring in the atmosphere.

Temperature measuring equipment should be placed in a shelter which protects it from mechanical damage and direct rays of the sun. The shelter should have louvered sides to permit free access of air. Aboard ship, the shelter should be placed in an exposed position as far as practicable from metal bulkheads. On vessels where shelters are not available, the temperature measurement should be made in shade at an exposed position on the windward side.

Sea water temperature is normally measured at the condenser intake. Although this is not a true measure of surface water temperature, the error is generally small. Measurement should be made near the entrance of the intake.

If the temperature of the water at the surface is desired, a sample should be obtained by bucket, preferably a canvas bucket, from a forward position well clear of any discharge lines. The sample should be taken immediately to a place where it is sheltered from wind and sun. The water should then be stirred with the thermometer, keeping the bulb submerged, until an essentially constant reading is obtained.

3713. Humidity is the condition of the atmosphere with reference to its water vapor content. **Absolute humidity** is a measure of the mass of vapor per unit volume of air. **Relative humidity** is the ratio (stated as a percentage) of the existing vapor pressure to the vapor pressure corresponding to saturation at the prevailing temperature and atmospheric pressure. This is very nearly the ratio of the amount of water vapor present to the amount that the air could hold at the same temperature and pressure if it were saturated.

As air cools, its capacity for holding water vapor decreases. Therefore, as air temperature decreases, the relative humidity increases. At some point, saturation takes place, and any further cooling results in condensation of some of the moisture. The temperature at which this occurs is called the **dew point,** and the moisture deposited upon natural objects is called **dew** if it forms in the liquid state, or **frost** if it forms in the frozen state.

The same process causes moisture to form on the outside of a container of cold liquid, the liquid cooling the air in the immediate vicinity of the container until it reaches the dew point. When moisture is deposited on man-made objects, it is usually called **sweat.** It occurs whenever the temperature of a surface is lower than the dew point of the air in contact with it. It is of particular concern to the mariner because of its effect upon his instruments, and possible damage to his ship or its cargo. Lenses of optical instruments may sweat, usually with such small droplets that the surface has a "frosted" appearance. When this occurs, the instrument is said to "fog" or "fog up," and is useless until the moisture is removed. Damage is often caused by corrosion or direct water damage when pipes sweat and drip, or when the inside of the shell plates of a vessel sweat. Cargo may sweat if it is cooler than the dew point of the air. One of the principal problems of preserving ships of the reserve fleet is the protection against moisture. An important step is the draining of all water, sealing of compartments, and drying of the air.

Clouds and fog form by "sweating" of minute particles of dust, salt, etc., in the air. Each particle forms a nucleus around which a droplet of water forms. If air is completely free from solid particles on which water vapor may condense, the extra moisture remains in the vapor state, and the air is said to be **supersaturated.**

Relative humidity and dew point are measured by means of a **hygrometer.** The most common type, called a **psychrometer,** consists of two thermometers mounted

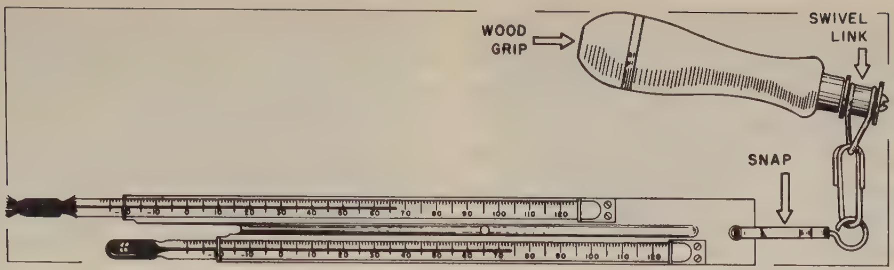

FIGURE 3713.—A sling psychrometer.

together on a single strip of material, as shown in figure 3713. One of the thermometers is mounted a little lower than the other, and has its bulb covered with muslin. When the muslin covering is thoroughly moistened and the thermometer well ventilated, evaporation cools the bulb of the thermometer, causing it to indicate a lower reading than the other. A **sling psychrometer,** illustrated in figure 3713, is ventilated by whirling the thermometers. Some psychrometers use a fan. **Dry-bulb temperature** is indicated by the uncovered **dry-bulb thermometer,** and **wet-bulb temperature** is indicated by the muslin-covered **wet-bulb thermometer.** The difference between these two temperatures, and the dry-bulb temperature, are used to enter **psychrometric tables** to find the relative humidity (tab. 16) and dew point (tab. 17). If the wet-bulb temperature is above freezing, reasonably accurate results can be obtained by a psychrometer consisting of wet- and dry-bulb thermometers mounted so that air can circulate freely around them without special ventilation. This type of installation is common aboard ship.

Example.—The dry-bulb temperature is 65°F and the wet-bulb temperature is 61°F.

Required.—(1) Relative humidity, (2) dew point.

Solution.—The difference between readings is 4°. Entering table 16 with this value and a dry-bulb temperature of 65°, the relative humidity is found to be 80 percent. From table 17 the dew point is found to be 58°.

Answers.—(1) Relative humidity 80 percent, (2) dew point 58°.

A recording hygrometer, called a **hygrograph,** provides a continuous record of relative humidity. In outward appearance this instrument is similar to a barograph (fig. 3705) and a thermograph (fig. 3712c), using the same clock movement and chart cylinder. The measuring element, however, generally consists of a number of strands of human hair separated into groups kept apart by a spreader device. The hairs are kept taut by a counterbalance. As the relative humidity rises, the hairs increase in length, and as the relative humidity falls, they decrease in length. A linkage magnifies these changes and transmits them to a pen which records the relative humidity on a chart placed around the clock-driven, revolving cylinder. The hygrograph is a convenient device, but lacks accuracy, lags considerably behind changes in relative humidity, and is not reliable at low temperatures. It requires frequent calibration.

A **hygrothermograph** combines the features of both the hygrograph and the thermograph, providing a continuous record of both relative humidity and air temperature for seven days on a single chart. It has the same limitations as the hygrograph and the thermograph and its indications should be checked daily by psychrometer and thermometer.

3714. Clouds are visible assemblages of numerous tiny droplets of water, or ice crystals, formed by condensation of water vapor in the air, with the bases of the assemblages above the surface of the earth. **Fog** is a similar assemblage in contact with the surface of the earth.

The shape, size, height, thickness, and nature of a cloud depend upon the conditions under which it is formed. Therefore, clouds are indicators of various processes occurring in the atmosphere. The ability to recognize different types and a knowledge of the conditions associated with them are useful in predicting future weather.

Although the variety of clouds is virtually endless, they may be classified according to general type. Clouds are grouped generally into four "families" according to some common characteristic. **High clouds** are those having a mean lower level above 20,000 feet. They are composed principally of ice crystals. **Middle clouds** have a mean level between 6,500 and 20,000 feet. They are composed largely of water droplets, although the higher ones have a tendency toward ice particles. **Low clouds** have a mean upper level of less than 6,500 feet. These clouds are composed entirely of water droplets. **Clouds with vertical development** are a distinctive group formed by rising air which is cooled as it reaches greater heights. When it reaches the height of the dew point, some of its water vapor condenses. Therefore, the bottoms of such clouds are usually flat. Clouds with vertical development may begin at almost any level, but generally within the low cloud range. They may extend to great heights, well above the lower limit of high clouds. They form as water droplets, but toward the top they may freeze.

Within these four families are ten principal cloud types. The names of these are composed of various combinations and forms of the following basic words, all from Latin:

Cirrus, meaning "curl."
Cumulus, meaning "heap."
Stratus, meaning "layer."
Alto, meaning "high."
Nimbus, meaning "rain."

The first three are the basic cloud types. Individual cloud types recognize certain characteristics, variations, or combinations of these. The ten principal cloud types are:

High clouds. **Cirrus** (**Ci**) are detached high clouds of delicate and fibrous appearance, without shading, generally white in color, and often of a silky appearance (figs. 3714a and 3714d). Their fibrous and feathery appearance is due to the fact that they are composed entirely of ice crystals. Cirrus appear in varied forms such as isolated tufts; long, thin lines across the sky; branching, feather-like plumes; curved wisps which may end in tufts, etc. These clouds may be arranged in parallel bands which cross the sky in great circles and appear to converge toward a point on the horizon. This may indicate, in a general way, the direction of a low pressure area. Cirrus may be brilliantly colored at sunrise and sunset. Because of their height, they become illuminated before other clouds in the morning, and remain lighted after others at sunset. Cirrus are generally associated with fair weather, but if they are followed by lower and thicker clouds, they are often the forerunner of rain or snow.

Cirrocumulus (**Cc**) are high clouds composed of small white flakes or scales, or of very small globular masses, usually without shadows and arranged in groups or lines, or more often in ripples resembling those of sand on the seashore (fig. 3714b). One form of cirrocumulus is popularly known as "mackerel sky" because the pattern resembles the scales on the back of a mackerel. Like cirrus, cirrocumulus are composed of ice crystals and are generally associated with fair weather, but may precede a storm if they thicken and lower. They may turn gray and appear hard before thickening.

Cirrostratus (**Cs**) are thin, whitish, high clouds (fig. 3714c) sometimes covering the sky completely and giving it a milky appearance and at other times presenting, more or less distinctly, a formation like a tangled web. The thin veil is not sufficiently dense to blur the outline of sun or moon. However, the ice crystals of which the cloud is

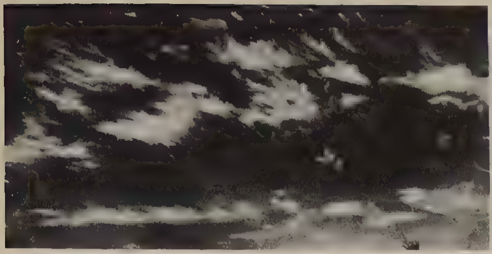

FIGURE 3714a.—Cirrus.

FIGURE 3714b.—Cirrocumulus.

FIGURE 3714c.—Cirrostratus.

FIGURE 3714d.—Cirrus and cirrostratus.

composed refract the light passing through in such a way that halos (art. 3819) may form with the sun or moon at the center. Figure 3714d shows cirrus thickening and changing into cirrostratus. In this form it is popularly known as "mares' tails." If it continues to thicken and lower, the ice crystals melting to form water droplets, the cloud formation is known as altostratus. When this occurs, rain may normally be expected within 24 hours. The more brushlike the cirrus when the sky appears as in figure 3714d, the stronger the wind at the level of the cloud.

Middle clouds. **Altocumulus** (**Ac**) are middle clouds consisting of a layer of large, ball-like masses that tend to merge together. The balls or patches may vary in thickness and color from dazzling white to dark gray, but they are more or less regularly arranged. They may appear as distinct patches (fig. 3714e) similar to cirrocumulus (fig. 3714b) but can be distinguished by the fact that individual patches are generally larger, and show distinct shadows in some places. They are often mistaken for stratocumulus (fig. 3714i). If this form thickens and lowers, it may produce thundery weather and showers, but it does not bring prolonged bad weather. Sometimes the patches merge to form a series of big rolls that resemble ocean waves, but with streaks of blue sky (fig. 3714f). Because of perspective, the rolls appear to run together near the horizon. These regular parallel bands differ from cirrocumulus in that they occur in larger masses with shadows. These clouds move in the direction of the short dimension of the rolls, as do ocean waves. Sometimes altocumulus appear briefly in the form shown in figure 3714g, usually before a thunderstorm. They are generally arranged in

FIGURE 3714e.—Altocumulus in patches.

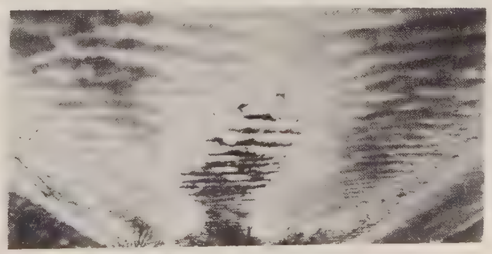

FIGURE 3714f.—Altocumulus in bands.

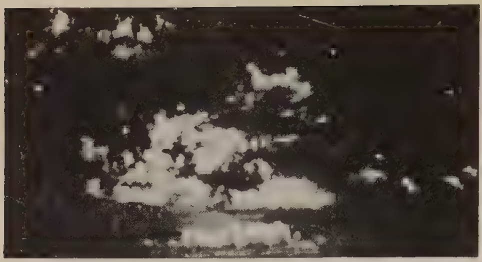

FIGURE 3714g.—Turreted altocumulus.

FIGURE 3714h.—Altostratus.

a line with a flat horizontal base, giving the impression of turrets on a castle. The turreted tops may look like miniature cumulus and possess considerable depth and great length. These clouds usually indicate a change to chaotic, thundery skies.

Altostratus (**As**) are middle clouds having the appearance of a grayish or bluish, fibrous veil or sheet (fig. 3714h). The sun or moon, when seen through these clouds, appears as if it were shining through ground glass, with a corona (art. 3820) around it. Halos are not formed. If these clouds thicken and lower, or if low, ragged "scud" or rain clouds (nimbostratus) form below them, continuous rain or snow may be expected within a few hours.

Low clouds. **Stratocumulus** (**Sc**) are low clouds composed of soft, gray, roll-shaped masses (fig. 3714i). They may be shaped in long, parallel rolls similar to altocumulus (fig. 3714f), moving forward with the wind. The motion is in the direction of their short dimension, like ocean waves. These clouds, which vary greatly in altitude, are the final product of the characteristic daily change that takes place in cumulus clouds. They are usually followed by clear skies during the night.

Stratus (**St**) is a low cloud in a uniform layer (fig. 3714j) resembling fog. Often the base is not more than 1,000 feet high. A veil of thin stratus gives the sky a hazy appearance. Stratus is often quite thick, permitting so little sunlight to penetrate that it appears dark to an observer below it. From above, it looks white. Light mist may descend from stratus. Strong wind sometimes breaks stratus into shreds called "fractostratus."

Nimbostratus (**Ns**) is a low, dark, shapeless cloud layer, usually nearly uniform, but sometimes with ragged, wet-looking bases. Nimbostratus is the typical rain cloud. The precipitation which falls from this cloud is steady or intermittent, but not showery.

Clouds with vertical development. **Cumulus** (**Cu**) are dense clouds with vertical development. They have a horizontal base and dome-shaped upper surface, with protuberances extending above the dome. Cumulus appear in small patches, and never cover the entire sky. When the vertical development is not great, the clouds appear in patches resembling tufts of cotton or wool, being popularly called "woolpack" clouds (fig. 3714k). The horizontal bases of such clouds may not be noticeable. These are

FIGURE 3714i.—Stratocumulus.

FIGURE 3714j.—Stratus.

FIGURE 3714k.—Cumulus.

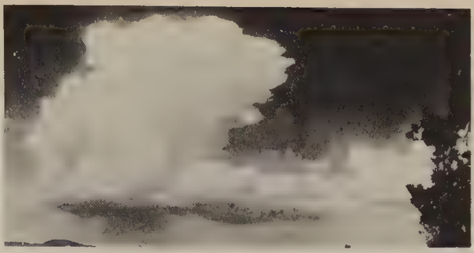

FIGURE 3714l.—Cumulonimbus.

called "fair weather" cumulus because they always accompany good weather. However, they may merge with altocumulus, or may grow to cumulonimbus before a thunderstorm. Since cumulus are formed by updrafts, they are accompanied by turbulence, causing "bumpiness" in the air. The extent of turbulence is proportional to the vertical extent of the clouds. Cumulus are marked by strong contrasts of light and dark.

Cumulonimbus (**Cb**) is a massive cloud with great vertical development, rising in mountainous towers to great heights (fig. 3714l). The upper part consists of ice crystals, and often spreads out in the shape of an anvil which may be seen at such distances that the base may be below the horizon. Cumulonimbus often produces showers of rain, snow, or hail, frequently accompanied by thunder. Because of this, the cloud is often popularly called a "thundercloud" or "thunderhead." The base is horizontal, but as showers occur it lowers and becomes ragged.

3715. Cloud height measurement.—At sea, cloud heights are often determined by estimate. This is a difficult task, particularly at night. A searchlight may be of some assistance. Radar operating at the higher frequencies, particularly three-centimeter radar, indicates returns from some clouds. Certain models permit measurement of height.

Ceiling balloons can be used to determine height of low clouds with reasonable accuracy. Any type balloon having a known rate of ascent is suitable. The following balloons are in use:

1. A 10-gram spherical balloon with 40 grams of hydrogen or 43 grams of helium. Used at Navy and Air Force stations.
2. A 10-gram spherical balloon with 45 grams of helium. Used at civil stations.
3. A 30-gram balloon with 125 grams of hydrogen or 139 grams of helium. Used at civil and Navy stations.
4. A 30-gram balloon with 132 grams of hydrogen or 147 grams of helium. Used at Air Force stations.

The ascent of these four balloons, in feet, is

Minutes	*1*	*2*	*3*	*4*
1	480	500	710	720
2	850	960	1, 360	1, 380
3	1, 210	1, 420	2, 010	2, 040
4	1, 570	1, 880	2, 630	2, 670
5	1, 930	2, 300	3, 250	3, 300
6	2, 290	2, 720	3, 840	3, 900
7	2, 650	3, 140	4, 430	4, 500
8	3, 010	3, 560	5, 020	5, 100.

For elapsed times greater than eight minutes, the rate is 360 feet per minute for balloon 1, 420 feet per minute for balloon 2, 590 feet per minute for balloon 3, and 600 feet per minute for balloon 4.

Cloud height is determined by measurement of the elapsed time from release of the balloon until it disappears in the clouds. Horizontal motion due to wind generally has negligible effect upon the rate of ascent.

The height of the base of clouds formed by vertical development (any form of cumulus), if formed in air that has risen from the surface of the earth, can be determined by psychrometer, because the height to which the air must rise before condensation takes place is proportional to the difference between surface air temperature and the dew point. At sea, this difference multiplied by 236 gives the height in feet. That is, for every degree difference between surface air temperature and the dew point, the air must rise 236 feet before condensation will take place. Thus, if the dry-bulb temperature is 80°F, and the wet-bulb temperature is 77°F, the dew point (from tab. 17) is 76°F, or four degrees lower than the surface air temperature. The height of the cloud base is $4 \times 236 = 944$ feet.

Ashore, cloud height measurement can be made at night by means of a **ceiling light projector** and **clinometer** (fig. 3715). The projector throws a beam of light vertically upward, casting a spot of light on the clouds. An observer at a known distance from the projector measures the angle of elevation of the spot of light. This is usually done by means of a clinometer, a single hand-held sighting device with a pointer

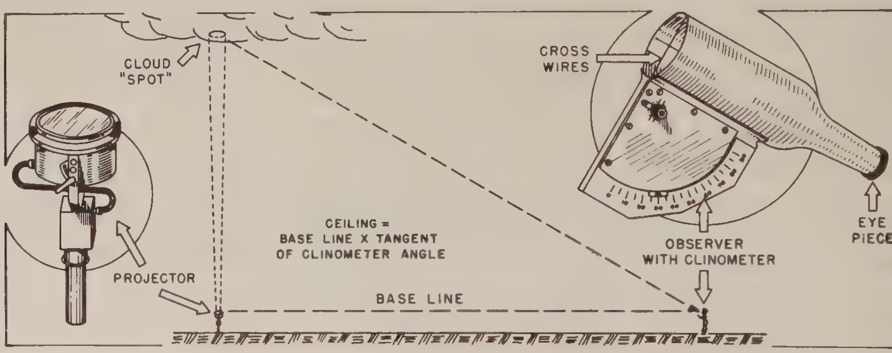

FIGURE 3715.—Ceiling light projector and clinometer for measuring cloud height at night.

which hangs freely and indicates elevation angle on an arc. The height of the cloud base is equal to the tangent of the elevation angle times the distance between the projector and observer, the curvature of the earth being neglected. Thus, if the observer is 400 feet from the projector, and the angle of elevation is 73°, the height of the base of the clouds is $400 \times 3.2709 = 1{,}308$ feet. If two ships are in company, an approximation of cloud height might be determined in this way, using a searchlight on one ship and a clinometer (a sextant can be used if the horizon is distinguishable) on the other. For low clouds, this might be performed on a single vessel, mounting the searchlight at one end of the vessel, and placing the observer at the other end. Reasonably accurate results might be obtained at sea if the searchlight can be stabilized in the vertical.

Measurements can be made both day and night by means of a **ceilometer.** This device consists of a projector, detector, and recorder to provide a continuous record of cloud height above the observing station, both day and night. The ceilometer uses a beam of light that is pulse modulated (art. 1016) like radar signals. The projector and detector are some distance apart, height being determined by the same principle used with the ceiling light projector and clinometer. Either the projector or detector continuously scans a 90° arc from the vertical to the horizontal, and back, in line with

the other instrument, which remains vertical. When the spot of light is in the line of sight of the detector, a photoelectric cell detects it, and actuates the recorder, which reads directly in height. The ceilometer is not suitable for use at sea.

3716. Visibility measurement.—**Visibility** is the extreme horizontal distance at which prominent objects can be seen and identified by the unaided eye. It is usually measured directly by the human eye. Ashore, the distances of various buildings, trees, lights, and other objects are measured and used as a guide in estimating the visibility. At sea, however, such an estimate is difficult to make with accuracy. Other ships and the horizon may be of some assistance.

Visibility is sometimes measured by a **transmissometer,** a device which measures the transparency of the atmosphere by passing a beam of light over a known short distance, and comparing it with a reference light.

3717. Upper air observations.—Upper air information provides the third dimension to the weather map. Unfortunately, the equipment necessary to obtain such information is quite expensive, and the observations are time consuming. Consequently, the network of observing stations is quite sparse compared to that for surface observations, particularly over the oceans and in isolated land areas. Where facilities exist, upper air observations are made by means of unmanned balloons in conjunction with theodolites, radiosondes, radar, and radio direction finders. Observations are sometimes made by aircraft.

3718. Pilot balloons are free balloons released at the surface of the earth and followed by optical means to determine their movement in relation to the point from which released. They are of neoprene latex (occasionally of natural rubber latex) a few thousandths of an inch thick, and have a nominal weight of either 30 or 100 grams. The balloons are inflated with helium or hydrogen to a definite free-lift capacity for which ascensional rate tables have been prepared. The neck of each balloon is then securely fastened to prevent leakage of the gas, and the balloon is released. A theodolite is trained on the balloon, which is kept in the field of vision of the instrument throughout the observation.

By means of a buzzer signal the observer is warned five seconds prior to the end of each minute after release. The cross hairs of the theodolite are then brought to bear on the balloon at the end of each minute (also signalled by the buzzer), and the horizontal and vertical angles are read to the nearest tenth of a degree. These data are then plotted on polar coordinate paper similar to a maneuvering board (art. 1212), and the wind speed and direction at each selected level (each 1,000-foot level) are determined.

An observation of winds aloft made in this manner is called a **pibal,** from **pil**ot **bal**loon observation. If the same procedure is used with a sounding balloon (art. 3720), the observation is called a **rabal,** from **ra**dio **bal**loon observation.

3719. The theodolite.—Survey theodolites are discussed in article 4004. The instrument by the same name used for pilot balloon observations is constructed on the same principle, but with some differences to suit the use for which it is intended.

The shore-type theodolite used by the meteorologist is essentially a telescope so mounted that the horizontal and vertical angles of its axis can be measured. The telescope is mounted in a yoke secured to a base plate. The base plate is mounted on a tripod or pipe support, with provision for accurate leveling. By means of a 45° prism, the line of sight is bent through an angle of 90°. The eyepiece is mounted on the horizontal axis of the theodolite. Tangent-screw controls permit adjustment in both the horizontal and vertical directions.

The shipboard-type theodolite (fig. 3719) differs considerably from the shore type, being mounted on gimbals atop a tripod. A counterbalance is provided to serve

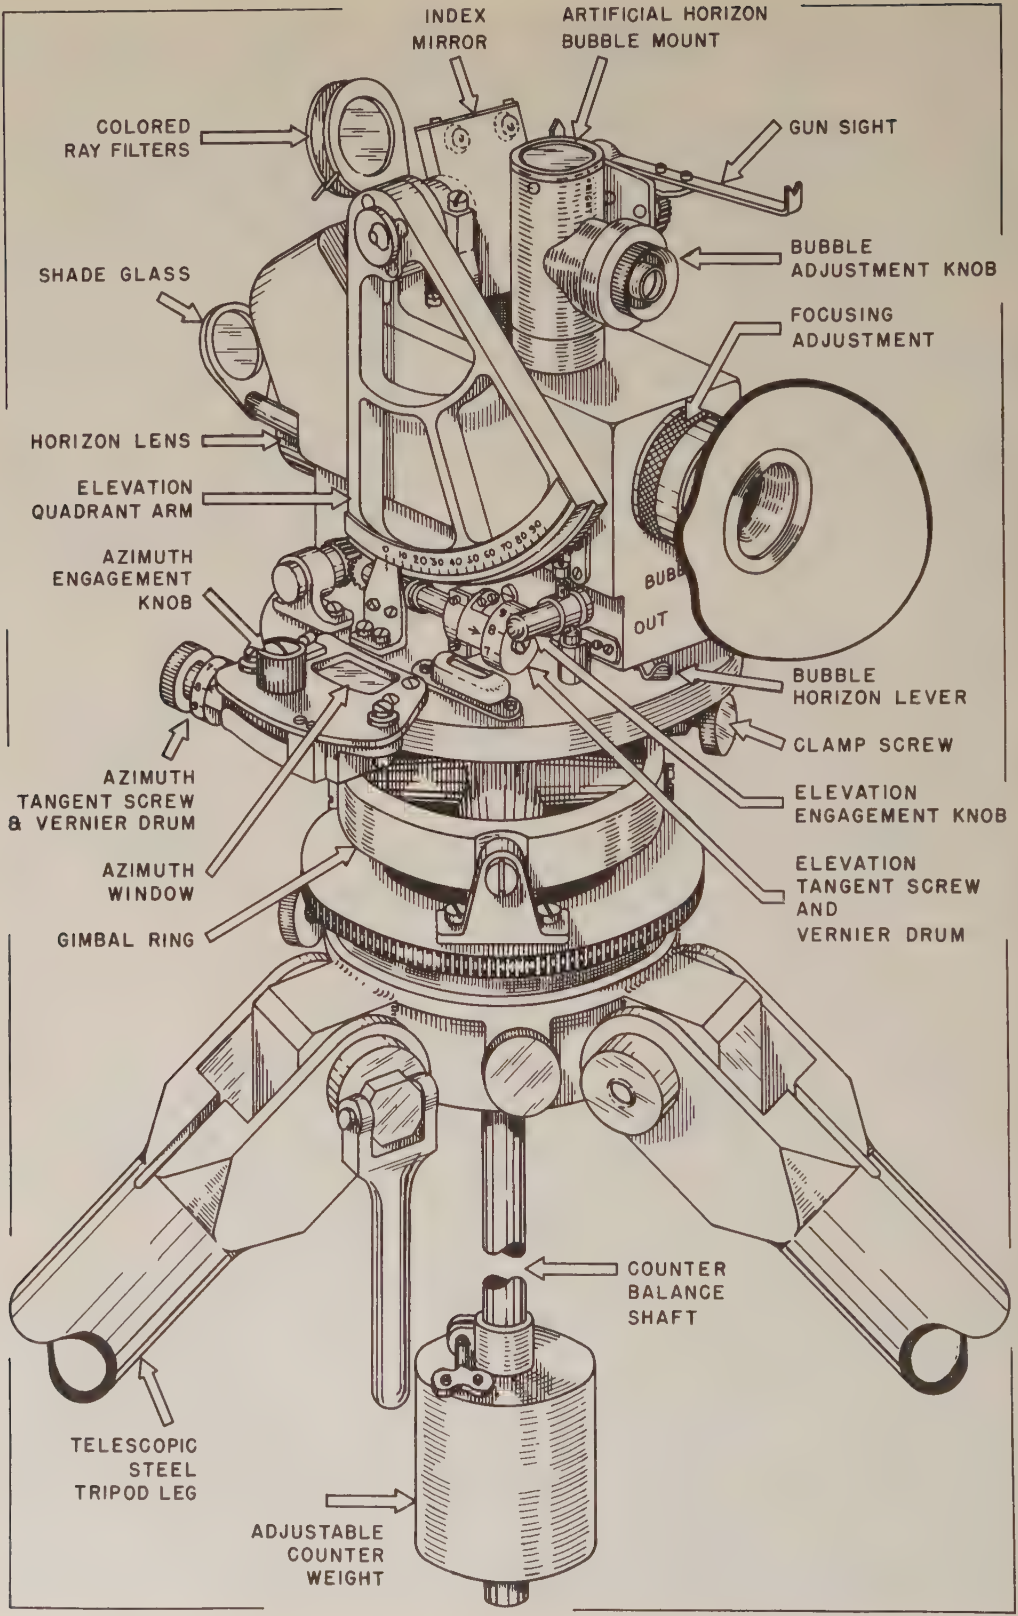

FIGURE 3719.—A shipboard-type meteorological theodolite.

as a pendulum in maintaining the instrument approximately horizontal. The instrument is aligned with the longitudinal axis of the craft, so that *relative* bearings are observed. Elevation angles are measured in a manner similar to the measurement of altitudes of celestial bodies, an image of the balloon being brought into coincidence with the direct view of the horizon. A bubble artificial horizon is also provided.

3720. Radiosondes are miniature radio transmitters carried aloft by **sounding balloons** which ascend at the rate of about 1,000 feet per minute, to a height of nearly 100,000 feet. The transmitter, powered by a compact battery, transmits on a frequency of 72, 403, or 1,680 megacycles per second. In the United States the 72-megacycle instruments have been replaced by 403-megacycle radiosondes.

As the radiosonde ascends, it transmits a continuous-wave radio signal on its assigned frequency. This signal is modulated (art. 1016) by pressure, temperature, and relative humidity in turn.

The transmitted radio signals are received by an antenna and radio receiver at the surface. They are fed through an electronic frequency meter, and then recorded. By this means a continuous record is made to the height at which the balloon bursts or its signals can no longer be received.

An observation made in this way is called a **raob,** from **ra**diosonde **ob**servation.

3721. Electronic measurement of winds aloft.—If either a pilot balloon (art. 3718) or sounding balloon (art. 3720) is fitted with a metal target and tracked by radar, height, slant distance, and bearing are available, permitting determination of wind speed and direction. Radio direction finder equipment which permits measurement of both horizontal and vertical directions has been developed and is in use ashore for tracking radiosondes. Similar equipment for use aboard ship is under development. An observation made by tracking with either radar or radio direction finder is called a **rawin,** from **ra**dio **win**ds-aloft observation. A combined raob (art. 3720) and rawin is called a **rawinsonde.**

3722. Observations by aircraft.—Reports from aircraft are helpful in making upper air observations. By this means, winds, heights of clouds, visibility, etc., can be determined. An aircraft flying over the ocean and equipped with both absolute and barometric altimeters can supply valuable information on the height of the pressure level at which it is flying. Such reports are used in connection with pressure pattern navigation (art. 2807). They are also useful in establishing positions of high and low pressure centers.

The Air Weather Service of the U. S. Department of Defense makes regular flights to collect weather information. These flights are made along established routes over the oceans and in the arctic where adequate coverage is not otherwise available. In addition, the U. S. Navy and U. S. Air Force, in cooperation with the Weather Bureau, make flights into tropical cyclones (ch. XXXIX) to collect useful information.

Prior to the advent of the radiosonde (art. 3720), an instrument known as the **aerograph** or **aerometeorograph** was widely used by most weather services. In effect, this instrument is a combination barograph (art. 3705), thermograph (art. 3712), and hygrograph (art. 3713). The instrument is attached to an aircraft, and during flight it makes a continuous trace of pressure, temperature, and relative humidity on a chart or "smoked sheet" attached to the drum of a clock-driven cylinder. By means of electrical connections to the pens, the pilot of the airplane indicates the time at which he enters and leaves phenomena such as haze, fog, clouds, rain, snow, etc. Since the heights reached are restricted by the ceiling of the aircraft, they are generally less than those attained by radiosondes. The use of the aerograph is now limited principally to storm reconnaissance.

3723. Storm detection radar.—During World War II, it was found that certain radar equipment gave an indication of weather fronts (art. 3812) and precipitation areas. It was of particular value near hurricanes and typhoons. Since the close of that war a great amount of work has been done in perfecting radar equipment for use in weather observation. It has proved of immense value in detecting, tracking, and interpreting weather activity out to a distance of as much as 400 miles from the observing station.

3724. Precipitation measurement.—Any type of condensed water vapor that falls to the earth's surface is called **precipitation.** It may be liquid, freezing, or frozen when it arrives at the surface. Measurement of precipitation normally includes only the determination of the amount of rain or snow that has fallen in a given period of time. For purposes of comparison, snow measurement is obtained by melting the snow to its water equivalent. Depth of snow is also measured to determine the amount of snowfall.

The usual type of **nonrecording precipitation gage** consists of a collector ring, funnel, and measuring cylinder set within a receiver. All precipitation falling on the area encompassed by the collector ring descends through the funnel into the measuring cylinder, where it is measured directly by means of a rod graduated in tenths of an inch. Since the cross-sectional area of the measuring cylinder is exactly one-tenth that of the collector ring, each 0.1 inch collected is a measure of 0.01 inch of precipitation. When precipitation is in the form of snow, the measuring tube is removed, permitting the snow to collect in the larger receiver. The receiver is placed in a container of warm water until the snow melts. The resulting liquid is then poured into the measuring tube and measured.

The most representative measurement of precipitation from snow is obtained by removing the collector ring and funnel, and using a slat screen to reduce the effect of wind.

One type of **recording rain gage** is known as the "tipping-bucket rain gage." The rainfall from a funnel-shaped collector is directed into one of two small buckets so arranged that when 0.01 inch of rain is collected, the bucket is forced downward, causing the other bucket to move into the collecting position. When a bucket is in the "down" position, its water runs into the base of the collector, where it can be measured later. As each bucket lowers in its turn, it causes a small cam to rotate into contact position and close a battery-powered electric circuit. This causes a magnetic relay at the recorder to operate a pen arm, which marks the additional 0.01 inch of rainfall on a chart secured to a clock-driven drum.

Another type of recording rain gage, used principally at locations which are not continuously attended, employs a weighing device which actuates a pen arm, causing it to trace measurements on a chart secured to a clock-driven drum.

The precipitation gage, whatever its form, should be placed in an exposed position as far as practicable from obstructions. Precipitation measurement is not ordinarily made aboard ship because the motions of the vessel, and the possibility of collecting salt spray, introduce errors into the measurement.

3725. Automatic weather stations provide regularly scheduled transmissions of meteorological measurements by radio. They are used at isolated and relatively inaccessible locations from which weather data are of great importance to the weather forecaster. The measurements usually obtained are of wind speed and direction, atmospheric pressure, temperature, and relative humidity.

3726. Recording observations.—Aboard ship, weather observations are recorded on the *Ship Weather Observation Sheet* (fig. 3726). Instructions for using this sheet are given in OPNAV Instruction 3140.37C, *Manual for Ship's Surface Weather Observations.*

FIGURE 3726.—Ship Weather Observation Sheet.

To assist in the preparation of synoptic observations for transmission, Table II (which is similar to WB Form 615–5, *Ship's Weather Observations*, for merchant ships which participate in the cooperative observation program of the U.S. Weather Bureau) is arranged in the correct code form with the five-digit groups separated by heavy lines. Two wave groups are given because two separate wave systems are sometimes persent.

The symbols to use in the "weather" column of Table I are as follows:

CLR	Clear or a few clouds
SCT	Scattered clouds—0.1 to 0.5 clouds
BKN	Broken clouds—0.6 to 0.9 clouds
OVC	Overcast—more than 0.9 clouds
T	Thunderstorm
R	Rain
RW	Rain showers
L	Drizzle
ZR	Freezing rain
ZL	Freezing drizzle
E	Sleet
F	Fog
GF	Shallow fog (ground fog)
EW	Sleet showers
S	Snow
SW	Snow showers
IC	Ice crystals
A	Hail
IF	Ice fog
H	Haze
K	Smoke
D	Dust
BY	Blowing spray

Problems

3709a. A ship is proceeding on course 180° at a speed of 22 knots. The apparent wind is from 70° off the port bow, speed 20 knots.

Required.—The relative direction, true direction, and speed of the true wind by maneuvering board or Weather Bureau plotter.

Answers.—True wind from 231° relative, 051° true, at 24.3 knots.

3709b. A ship is proceeding on course 050° at a speed of 13.5 knots. The apparent wind is from broad on the starboard bow, speed 20 knots.

Required.—The relative direction, true direction, and speed of the true wind by table 10.

Answers.—True wind from 086° relative, 136° true, at 14.3 knots.

3709c. A ship is proceeding on course 020° at a speed of 16 knots. The true wind is estimated to be from 110° on the port bow, speed 10 knots.

Required.—The relative direction, true direction, and speed of the apparent wind by maneuvering board or Weather Bureau plotter.

Answers.—Apparent wind from 323° relative, 343° true, at 15.6 knots.

3709d. A ship is proceeding on course 190° at a speed of 14 knots. The true wind is estimated to be from broad on the starboard quarter, speed 20 knots.

Required.—The relative direction, true direction, and speed of the apparent wind by table 10.

Answers.—Apparent wind from 090° relative, 280° true, at 14.0 knots.

3709e. The true wind has been determined to be from 210°, speed 12 knots. The captain of an aircraft carrier desires an apparent wind of 30 knots from 10° on the port bow for launching aircraft.

Required.—The course and speed of the aircraft carrier.

Answers.—C 235°, S 18.6 kn. (The required apparent wind could also be produced by C 005°, S 40.5 kn.)

3709f. A ship is proceeding on course 255° at a speed of 15 knots. The wind vane indicates the apparent wind is broad on the starboard beam. From the appearance of the sea the navigator estimates the speed of the true wind as Beaufort 5 (19 knots).

Required.—(1) Relative and true directions of the true wind, (2) speed of the apparent wind. Use the maneuvering board.

Answers.—(1) True wind from 142° relative, 037° true; (2) apparent wind speed 11.6 knots.

3709g. A ship is proceeding on course 135° at a speed of 18 knots. The wind vane indicates the apparent wind is 40° on the starboard bow. From the appearance of the sea the navigator estimates the speed of the true wind as Beaufort 6 (24.5 knots).

Required.—(1) Relative and true directions of the true wind, (2) speed of the apparent wind. Use table 10.

Answers.—(1) True wind from 069° relative, 204° true; (2) apparent wind speed 36 knots.

3709h. A ship is proceeding on course 330° at a speed of 20 knots. The wind vane indicates the apparent wind is 30° on the port bow. From the appearance of the sea the navigator estimates the speed of the true wind as Beaufort 4 (13.5 knots).

Required.—(1) Relative and true directions of the true wind, (2) speed of the apparent wind. Solve first by maneuvering board and then by table 10.

Answers.—Graphical solution: (1) true wind from 199° relative, 169° true or from 282° relative, 252° true; (2) apparent wind speed 8.5 knots or 26.3 knots. Table 10 solution: (1) true wind from 197° relative, 167° true or from 283° relative, 253° true; (2) apparent wind speed 8.0 knots or 26.0 knots.

3713. The dry-bulb temperature is 41° F and the wet-bulb temperature is 35° F.

Required.—(1) Relative humidity, (2) dew point.

Answers.—(1) Relative humidity 53 percent, (2) dew point 26°.

3715a. A 30-gram balloon with 139 grams of helium is released, and 10^m12^s later it disappears in the clouds.

Required.—Height of the base of the clouds.

Answer.—Height 6,318 feet.

3715b. The dry-bulb temperature is 72° F and the wet-bulb temperature is 58° F.

Required.—Height of the base of cumulonimbus clouds formed in air which has risen from the surface of the sea.

Answer.—Height 5,900 feet.

3715c. An observer 1,000 feet from a ceiling light projector measures the elevation angle of the spot of light on the base of the clouds as 68°.

Required.—Height of the base of the clouds.

Answer.—Height 2,475 feet.

CHAPTER XXXVIII

WEATHER AND WEATHER FORECASTS

3801. Introduction.—**Weather** is the state of the earth's atmosphere with respect to temperature, humidity, precipitation, visibility, cloudiness, etc. In contrast, the term **climate** refers to the prevalent or characteristic meteorological conditions of a place or region.

All weather may be traced ultimately to the effect of the sun on the earth, including the lower portions of the atmosphere. Most changes in weather involve large-scale, approximately horizontal, motion of air. Air in such motion is called **wind.** This motion is produced by differences of atmospheric pressure, which are largely attributable to differences of temperature.

The weather is of considerable interest to the mariner. The wind and state of the sea affect dead reckoning. Reduced horizontal visibility limits piloting. The state of the atmosphere affects electronic navigation and radio communication. If the skies are overcast, visual celestial observations are not available; and under certain conditions refraction and dip are disturbed. When wind was the primary motive power, knowledge of the areas of favorable winds was of great importance. This consideration led Matthew Fontaine Maury, more than a century ago, to seek information from ships' logs to establish speed and direction of prevailing winds over the various trade routes of the world. The information thus gathered was shown on pilot charts. By means of these charts, the mariner could select a suitable route for a favorable passage. Even power vessels are affected considerably by wind and sea. Less fuel consumption and a more comfortable passage are to be expected if wind and sea are moderate and favorable. Pilot charts are useful in selecting suitable routes. Since longer range forecasts have become possible, some experimental work has been done in routing ocean vessels to take advantage of anticipated conditions during passage.

3802. The atmosphere is a relatively thin shell of air, water vapor, dust, smoke, etc., surrounding the earth. The air is a mixture of transparent gases (art. 1410) and, like any gas, is elastic and highly compressible. Although extremely light, it has a definite weight which can be measured. A cubic foot of air at standard sea-level temperature and pressure weighs 1.22 ounces, or about 1/817th part of the weight of an equal volume of water. Because of this weight, the atmosphere exerts a pressure upon the surface of the earth, amounting to about 15 pounds per square inch.

As altitude increases, less atmosphere extends upward, and pressure decreases. With less pressure, the density decreases. More than three-fourths of the air is concentrated within a layer averaging about seven statute miles thick, called the **troposphere.** This is the region of most "weather," as the term is commonly understood.

The top of the troposphere is marked by a thin transition zone called the **tropopause.** Beyond this lie several other layers having distinctive characteristics, as listed in article 1410, and shown in figure 1410. The average height of the tropopause ranges from about five miles or less over the poles to about 11 miles over the equator.

The **standard atmosphere** is a conventional vertical structure of the atmosphere characterized by standard sea level pressure of 29.92 inches of mercury (1013.25 millibars), sea level temperature of 59°F (15°C), and a uniform decrease of temperature

and moisture content of the air with height, the rate of temperature decrease being 3°6 F (2°C) per thousand feet to 11 kilometers (36,089 feet) and thereafter a constant temperature of (−)69°7 F (−56°5 C). The rate of temperature decrease with height in the standard atmosphere is called the **standard temperature lapse rate.**

Meteorologists are continually learning more of the characteristics of atmospheric processes above the lowest portions of the atmosphere. In recent years, greatly increased attention has been directed to such features as the **jet stream,** a meandering stream of air which circles the globe at speeds of 100 to more than 250 knots at heights of about 20,000 to 40,000 feet. Some similarity has been noted between major wind streams such as the jet stream, and ocean currents such as the Gulf Stream (art. 3206).

3803. Wind.—When air is not confined, changes in temperature produce changes in volume, heated air expanding and cooled air contracting. If a large volume of air near the surface of the earth is cooled, it contracts, causing a downdraft. Air from neighboring regions aloft moves horizontally to fill the void. This results in a greater mass of air over the region, and the pressure is correspondingly increased. By a similar process in reverse, heating of air near the surface causes expansion and an updraft, resulting in decreased pressure over the heated area. Near the surface of the earth, the air tends to move from an area of high pressure to one of low pressure. Thus, a circulation is set up, air moving across the surface of the earth from an area of high pressure and low temperature to one of low pressure and high temperature, then vertically upward, then horizontally at high altitudes from the area of low pressure to that of high pressure, where it moves vertically downward to complete the circuit. The actual circulation is much more complex than this, due to such factors as rotation of the earth and continual changes in temperature and pressure.

If there were no heating and cooling, the temperature at any given altitude remaining everywhere the same, there would be no tendency for the air to move from one place to another. Air would lie sluggish and at rest on the earth's surface. There would be no wind and no variation in weather.

As a result of the position and motion of the earth in relation to the sun, and the physical processes involving radiation and absorption of energy, certain regions of the earth are always warmer than others. For similar reasons, the air over some parts of the earth is seasonally warmer than that over other parts. This general pattern is modified to a varying degree by the local heating and cooling which is continually taking place. Consequently, winds in some areas are relatively steady in both direction and speed, others are seasonal, and this general circulation is continually being modified by local conditions.

3804. General circulation of the atmosphere.—The heat required for warming the air is supplied originally by the sun. As radiant energy from the sun arrives at the earth, about 43 percent is reflected back into space by the atmosphere, about 17 percent is absorbed in the lower portions of the atmosphere, and the remaining 40 percent (approximately) reaches the surface of the earth and much of it is reradiated into space. This earth radiation is in comparatively long waves relative to the short-wave radiation from the sun, since it emanates from a cooler body. Long-wave radiation, being readily absorbed by the water vapor in the air, is primarily responsible for the warmth of the atmosphere near the earth's surface. Thus, the atmosphere acts much like the glass on the roof of a greenhouse. It allows part of the incoming solar radiation to reach the surface of the earth, but is heated by the terrestrial radiation passing outward. Over the entire earth and for long periods of time, the total outgoing energy must be equivalent to the incoming energy (minus any converted to another form and retained), or the temperature of the earth, including its atmosphere, would steadily increase or decrease. In local areas, or over relatively short periods of time,

such a balance is not required, and in fact does not exist, resulting in changes such as those occurring in the different seasons, and in different parts of the day.

As shown in figure 1419b, the more nearly perpendicular the rays of the sun strike the surface of the earth, the more heat energy per unit area is received at that place. Physical measurements show that in the tropics more heat per unit area is received than is radiated away, and that in polar regions the opposite is true. Unless there were some process to transfer heat from the tropics to polar regions, the tropics would be much warmer than they are, and the polar regions would be much colder. The process which brings about the required transfer of heat is the general circulation of the atmosphere.

If the earth had a uniform surface, did not rotate on its axis (but received sunlight equally all around the equator), and did not revolve around the sun (with its axis tilted), a simple circulation would result, as shown in figure 3804a. However, the surface of the earth is far from uniform, being covered with an irregular distribution of land of various heights, and water; the earth rotates about its axis once in approximately 24 hours, so that the portion heated by the sun continually changes; and the axis of rotation is tilted so that as the earth moves along its orbit about the sun, seasonal changes occur in the exposure of specific areas to the sun's rays, resulting in variations in the heat balance of these areas. These factors, coupled with others, result in constantly changing large-scale movements of air. Based upon averages over long periods, however, a general circulation is discernible. Figures 3804b and 3804c give a generalized picture of the world's pressure distribution and wind systems as actually observed. A simplified diagram of the general pattern is shown in figure 3804d.

The rotation of the earth diverts the air from a direct path between high and low pressure areas, the diversion being toward the *right* in the northern hemisphere and toward the *left* in the southern hemisphere. At some distance above the surface of the

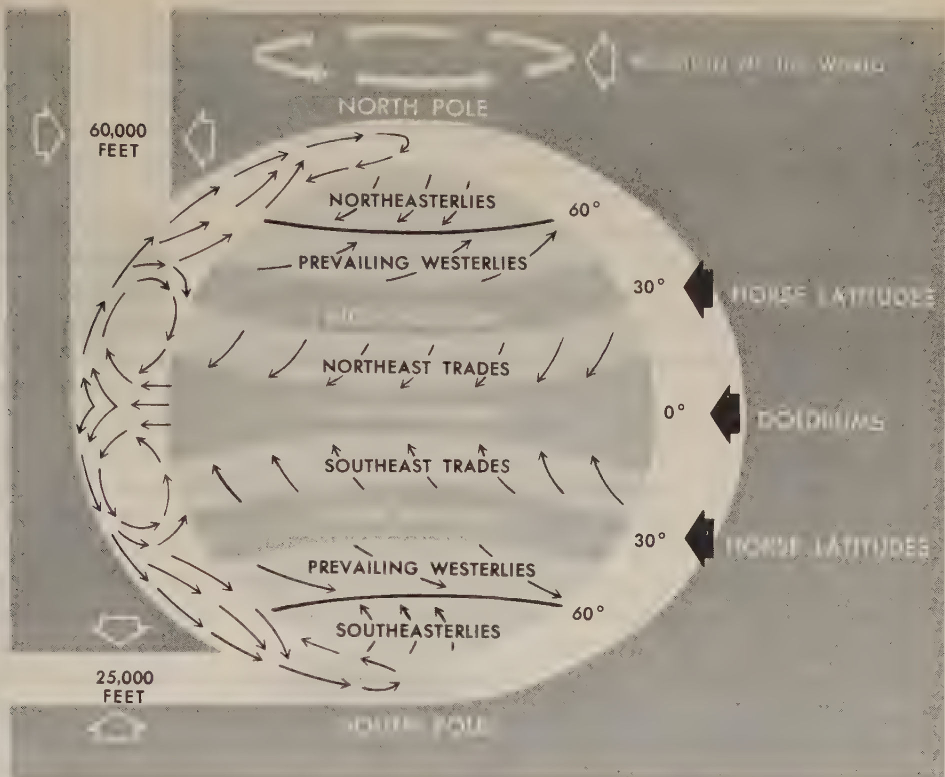

FIGURE 3804d.—Simplified diagram of the general circulation of the atmosphere.

earth, the wind tends to blow along the isobars, being called the **geostrophic wind** if the isobars are straight (great circles), and **gradient wind** if they are curved. Near the surface of the earth, friction tends to divert the wind from the isobars toward the center of low pressure. At sea, where friction is less than on land, the wind follows the isobars more closely.

The decrease of pressure with distance is called the **pressure gradient.** It is maximum along a normal (perpendicular) to the isobars, decreasing to zero along the isobars. Speed of the wind is directly proportional to the maximum pressure gradient.

3805. The doldrums.—The belt of low pressure near the equator occupies a position approximately midway between high pressure belts at about latitude 30° to 35° on each side. Except for slight diurnal changes, the atmospheric pressure along the equatorial low is almost uniform. With almost no pressure gradient, wind is practically nonexistent. The light breezes that do blow are variable in direction. Hot, sultry days are common. The sky is often overcast, and showers and thundershowers are relatively frequent.

The area involved is a thin belt near the equator, the eastern part in both the Atlantic and Pacific being wider than the western part. However, both the position and extent of the belt vary somewhat with the season. During February and March it lies immediately to the north of the equator and is so narrow that it may be considered virtually nonexistent. In July and August the belt is centered on about latitude 7° N, and is several degrees in width, even at the narrowest point.

3806. The trade winds blow from the belts of high pressure, toward the equatorial belt of low pressure. Because of the rotation of the earth, the moving air is deflected

toward the west. Therefore, the trade winds in the northern hemisphere are from the northeast and are called the **northeast trades,** while those in the southern hemisphere are from the southeast and are called the **southeast trades.** Over the eastern part of both the Atlantic and Pacific these winds extend considerably farther from the equator, and their original direction is more nearly along the meridians, than in the western part of each ocean.

The trade winds are generally considered among the most constant of winds. Although they sometimes blow for days or even weeks with little change of direction or speed, their constancy is sometimes exaggerated. At times they weaken or shift direction, and there are regions where the general pattern is disrupted. A notable example is the island groups of the South Pacific, where they are practically nonexistent during January and February. Their highest development is attained in the South Atlantic and in the South Indian Ocean. Everywhere they are fresher during the winter than during the summer.

In July and August, when the belt of equatorial low pressure moves to a position some distance north of the equator, the southeast trades blow across the equator, into the northern hemisphere, where the earth's rotation diverts them toward the right, causing them to be southerly and southwesterly winds. The "southwest monsoons" of the African and Central American coasts have their origin partly in such diverted southeast trades.

Cyclonic storms generally do not enter the regions of the trade winds, although hurricanes and typhoons (ch. XXXIX) may originate within these areas.

3807. The horse latitudes.—Along the poleward side of each trade-wind belt, and corresponding approximately with the belt of high pressure in each hemisphere, is another region with weak pressure gradients and correspondingly light, variable winds. These are called the **horse latitudes.** The weather is generally clear and fresh, unlike that in the doldrums, and periods of stagnation are less persistent, being of a more intermittent nature. The difference is due primarily to the fact that rising currents of warm air in the equatorial low carry large amounts of moisture which condenses as the air cools at higher levels, while in the horse latitudes the air is apparently descending and becoming less humid as it is warmed at lower heights.

3808. The prevailing westerlies.—On the poleward side of the high pressure belt in each hemisphere the atmospheric pressure again diminishes. The currents of air set in motion along these gradients toward the poles are diverted by the earth's rotation toward the east, becoming southwesterly winds in the northern hemisphere and northwesterly in the southern hemisphere. These two wind systems are known as the **prevailing westerlies** of the temperate zones.

In the northern hemisphere this relatively simple pattern is distorted considerably by secondary wind circulations, due primarily to the presence of large land masses. In the North Atlantic, between latitudes 40° and 50°, winds blow from some direction between south and northwest during 74 percent of the time, being somewhat more persistent in winter than in summer. They are stronger in winter, too, averaging about 25 knots (Beaufort 6) as compared with 14 knots (Beaufort 4) in the summer.

In the southern hemisphere the westerlies blow throughout the year with a steadiness approaching that of the trade winds (art. 3806). The speed, though variable, is generally between 17 and 27 knots (Beaufort 5 and 6). Latitudes 40°S to 50°S (or 55°S) where these boisterous winds occur, are called the **roaring forties.** These winds are strongest at about latitude 50°S.

The greater speed and persistence of the westerlies in the southern hemisphere are due to the difference in the atmospheric pressure pattern, and its variations, from that of the northern hemisphere. In the comparatively landless southern hemisphere,

the average yearly atmospheric pressure diminishes much more rapidly on the poleward side of the high pressure belt, and has fewer irregularities due to continental interference, than in the northern hemisphere.

3809. Winds of polar regions.—Because of the low temperatures near the geographical poles of the earth, the pressure tends to remain higher than in surrounding regions. Consequently, the winds blow outward from the poles, and are deflected westward by the rotation of the earth, to become **northeasterlies** in the arctic, and **southeasterlies** in the antarctic. Where these meet the prevailing westerlies, the winds are variable.

In the arctic, the general circulation is greatly modified by surrounding land masses. Winds over the Arctic Ocean are somewhat variable, and strong surface winds are rarely encountered.

In the antarctic, on the other hand, a high central land mass is surrounded by water, a condition which augments, rather than diminishes, the general circulation. The high pressure, although weaker than in some areas, is stronger than in the arctic, and of great persistence near the south pole. The upper air descends over the high continent, where it becomes intensely cold. As it moves outward and downward toward the sea, it is deflected toward the west by the earth's rotation. The winds remain strong throughout the year, frequently attaining hurricane force, and sometimes reaching speeds of 100 to 200 knots at the surface. These are the strongest surface winds encountered anywhere in the world, with the possible exception of those in well-developed tropical cyclones (ch. XXXIX).

3810. Modifications of the general circulation.—The general circulation of the atmosphere as described in articles 3804–3809 is greatly modified by various conditions.

The high pressure in the horse latitudes is not uniformly distributed around the belts, but tends to be accentuated at several points, as shown in figures 3804b and 3804c. These **semipermanent highs** remain at about the same places with great persistence.

Semipermanent lows also occur in various places, the most prominent ones being west of Iceland, and over the Aleutians (winter only) in the northern hemisphere, and at the Ross Sea and Weddell Sea in the antarctic. The areas occupied by these semipermanent lows are sometimes called the graveyards of the lows, since many lows move directly into these areas and lose their identity as they merge with and reinforce the semipermanent lows. The low pressure in these areas is maintained largely by the migratory lows which stall there, but partly by the sharp temperature difference between polar regions and warmer ocean areas.

Another modifying influence is land, which undergoes greater temperature changes than does the sea. During the summer, a continent is warmer than its adjacent oceans. Therefore, low pressures tend to prevail over the land. If a belt of high pressure encounters such a continent, its pattern is distorted or interrupted. A belt of low pressure is intensified. The winds associated with belts of high and low pressure are distorted accordingly. In winter, the opposite effect takes place, belts of high pressure being intensified over land and those of low pressure being interrupted.

The most striking example of a wind system produced by the alternate heating and cooling of a land mass is the **monsoons** of the China Sea and Indian Ocean. A portion of this effect is shown in figures 3810a and 3810b. In the summer (fig. 3810a), low pressure prevails over the warm continent of Asia, and high pressure over the adjacent sea. Between these two systems the wind blows in a nearly steady direction. The lower portion of the pattern is in the southern hemisphere, extending to about 10° south latitude. Here the rotation of the earth causes a deflection to the left, resulting in southeasterly winds. As they cross the equator, the deflection is in the opposite direction, causing them to curve toward the right, becoming southwesterly

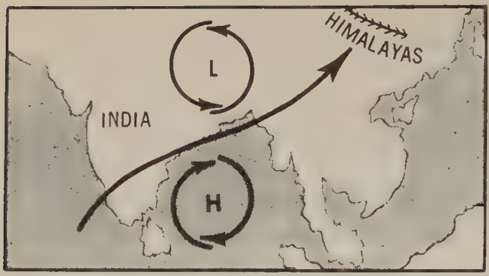

FIGURE 3810a.—The summer monsoon.

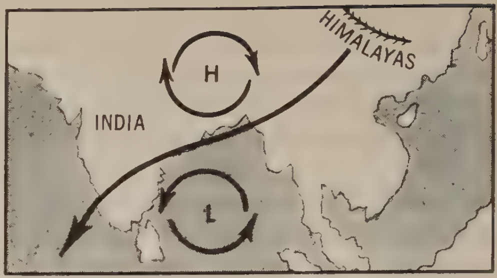

FIGURE 3810b.—The winter monsoon.

winds. In the winter (fig. 3810b), the positions of high and low pressure areas are interchanged, and the direction of flow is reversed.

In the China Sea the summer monsoon blows from the southwest, usually from May to September. The strong winds are accompanied by heavy squalls and thunderstorms, the rainfall being much heavier than during the winter monsoon. As the season advances, squalls and rain become less frequent. In some places the wind becomes a light breeze which is unsteady in direction, or stops altogether, while in other places it continues almost undiminished, with changes in direction or calms being infrequent. The winter monsoon blows from the northeast, usually from October to April. It blows with a steadiness similar to that of the trade winds, often attaining the speed of a moderate gale (28–33 knots). Skies are generally clear during this season, and there is relatively little rain.

The general circulation is further modified by winds of cyclonic origin (art. 3813), and various local winds (art. 3814).

3811. Air masses.—Because of large differences in physical characteristics of the earth's surface, particularly the oceanic and continental contrasts, the air overlying these surfaces acquires differing values of temperature, moisture, etc. The processes of radiation and convection in the lower portions of the troposphere act in differing, characteristic manners for a number of well-defined regions of the earth. The air overlying these regions acquires characteristics common to the particular area, but contrasting to those of other areas. Each distinctive part of the atmosphere, within which common characteristics prevail over a reasonably large area, is called an **air mass.**

Air masses are named according to their source regions. Four such regions are generally recognized: (1) *equatorial* (E), the doldrum area between the north and south trades; (2) *tropical* (T), the trade wind and lower temperate regions; (3) *polar* (P), the higher temperate latitudes; and (4) *arctic* (A), the north polar region of ice and snow (or, by extension, the antarctic). This classification is a general indication of relative temperature, as well as latitude of origin.

Tropical and polar air masses are further classified as *maritime* (m) or *continental* (c), depending upon whether they form over water or land. This classification is an indication of the relative moisture content of the air mass. Since the moisture content of equatorial and arctic air is essentially independent of the surface over which they form, these sub-classifications are not applied to them. Tropical air, then, might be designated *maritime tropical* (mT) or *continental tropical* (cT). Similarly, polar air may be either *maritime polar* (mP) or *continental polar* (cP).

A third classification sometimes applied to tropical and polar air masses indicates whether the air mass is *warm* (w) or *cold* (k) relative to the underlying surface. Thus, the symbol mTw indicates maritime tropical air which is warmer than the under-

lying surface, and *cPk* indicates continental polar air which is colder than the underlying surface. The *w* and *k* classifications are primarily indications of stability. If the air is cold relative to the surface, the lower portion of the air mass is being heated, resulting in instability as the warmer air tends to rise by convection. Conversely, if the air is warm relative to the surface, the lower portion of the air mass is cooled, tending to remain close to the surface. This is a stable condition.

Two other types of air masses are sometimes recognized. These are *monsoon* (*M*), a transitional form between *cP* and *E*; and *superior* (*S*), a special type formed in the free atmosphere by the sinking and consequent warming of air aloft.

3812. Fronts.—As air masses move within the general circulation, they travel from their source regions and invade other areas dominated by air having different characteristics. There is little tendency for adjacent air masses to mix. Instead, they are separated by a thin zone in which air mass characteristics exhibit such sharp gradients as to appear as discontinuities. This is called a **frontal surface.** The intersection of a frontal surface and a horizontal plane is called a **front,** although the term "front" is commonly used as a short expression for "frontal surface" when this will not introduce an ambiguity.

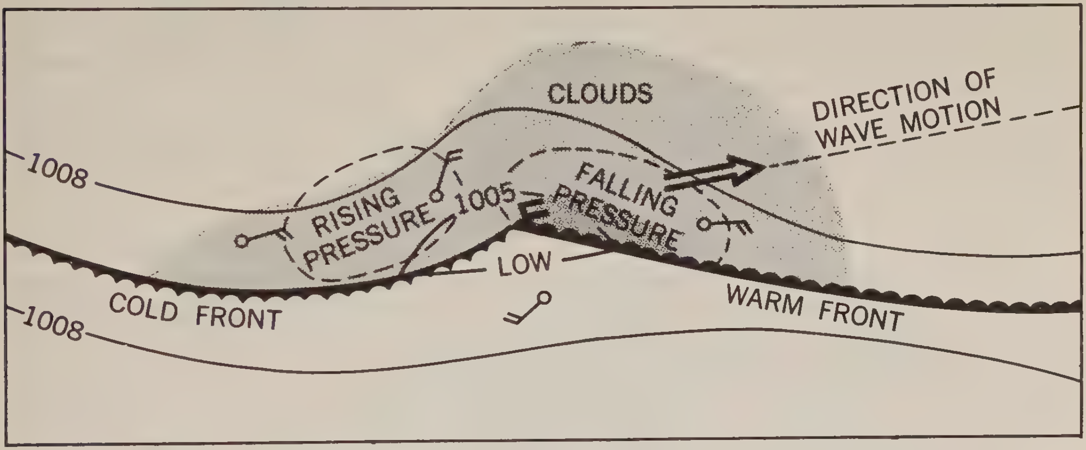

FIGURE 3812a.—First stage in the development of a frontal wave (top view).

Because of differences in the motion of adjacent air masses, "waves" form along the frontal surface between them.

Before the formation of frontal waves, the isobars (lines of equal atmospheric pressure) tend to run parallel to the fronts. As a wave is formed, the pattern is distorted somewhat, as shown in figure 3812a. In this illustration, colder air is north of warmer air. Isobars are shown at intervals of three millibars. The wave tends to travel in the direction of the general circulation, which in the temperate latitudes is usually in a general easterly and slightly poleward direction.

Along the leading edge of the wave, warmer air is replacing colder air. This is called the **warm front.** The trailing edge is the **cold front,** where colder air is replacing warmer air.

The warm air, being less dense, tends to ride up over the colder air it is replacing, causing the warm front to be tilted in the direction of motion. The slope is gentle, varying between 1:100 and 1:300. Because of the replacement of cold, dense air with warm, light air, the pressure decreases. Since the slope is gentle, the upper part of a warm frontal surface may be many hundreds of miles ahead of the surface portion. The decreasing pressure, indicated by a "falling barometer," is often an indication of

the approach of such a wave. In a slow-moving, well-developed wave, the barometer may begin to fall several *days* before the wave arrives. Thus, the amount and nature of the change of atmospheric pressure between observations, called **pressure tendency,** is of assistance in predicting the approach of such a system.

The advancing cold air, being more dense, tends to cut under the warmer air at the cold front, lifting it to greater heights. The slope here is in the opposite direction, at a rate of about 1:25 to 1:100, being steeper than the warm front. Therefore, after a cold front has passed, the pressure increases—a "rising barometer."

In the first stages, these effects are not marked, but as the wave continues to grow, they become more pronounced, as shown in figure 3812b. As the amplitude of the wave increases, pressure near the center usually decreases, and the "low" is said to "deepen." As it deepens, its forward speed generally decreases.

The approach of a well-developed warm front is usually heralded not only by falling pressure, but also by a more-or-less regular sequence of clouds. First, cirrus appear. These give way successively to cirrostratus, altostratus, altocumulus, and nimbostratus. Brief showers may precede the steady rain accompanying the nimbostratus.

As the warm front passes, the temperature rises, the wind shifts to the right (in the northern hemisphere), and the steady rain stops. Drizzle may fall from low-lying stratus clouds, or there may be fog for some time after the wind shift. During passage of the **warm sector** between the warm front and the cold front, there is little change in temperature or pressure. However, if the wave is still growing and the low deepening, the pressure might slowly decrease. In the warm sector the skies are generally clear or partly cloudy, with cumulus or stratocumulus clouds most frequent. The warm air is usually moist, and haze or fog may often be present.

As the faster moving, steeper cold front passes, the wind shifts abruptly to the right (in the northern hemisphere), the temperature falls rapidly, and there are often brief and sometimes violent showers, frequently accompanied by thunder and lightning. Clouds are usually of the convective type. A cold front usually coincides with a well-defined **wind-shift line** (a line along which the wind shifts abruptly from southerly or southwesterly to northerly or northwesterly in the northern hemisphere and from northerly or northwesterly to southerly or southwesterly in the southern hemisphere). At sea a series of brief showers accompanied by strong, shifting winds may occur along or some distance (up to 200 miles) ahead of a cold front. These are called **squalls,** and the line along which they occur is called a **squall line.** Because of its greater speed and steeper slope, which may approach or even exceed the vertical near the earth's surface (due to friction), a cold front and its associated weather passes more quickly than a warm front. After a cold front passes, the pressure rises, often quite rapidly, the visibility usually improves, and the clouds tend to diminish.

As the wave progresses and the cold front approaches the slower moving warm front, the low becomes deeper and the warm sector becomes smaller. This is shown in figure 3812c.

Finally, the faster moving cold front overtakes the warm front (fig. 3812d), resulting in an **occluded front** at the surface, and an **upper front** aloft (fig. 3812e). When the two parts of the cold air mass meet, the warmer portion tends to rise above the colder part. The warm air continues to rise until the entire system dissipates. As the warmer air is replaced by colder air, the pressure gradually rises, a process called "filling." This usually occurs within a few days after an occluded front forms, but the process is sometimes delayed by a slowing of the forward motion of the wave. In general, however, a filling low increases in speed.

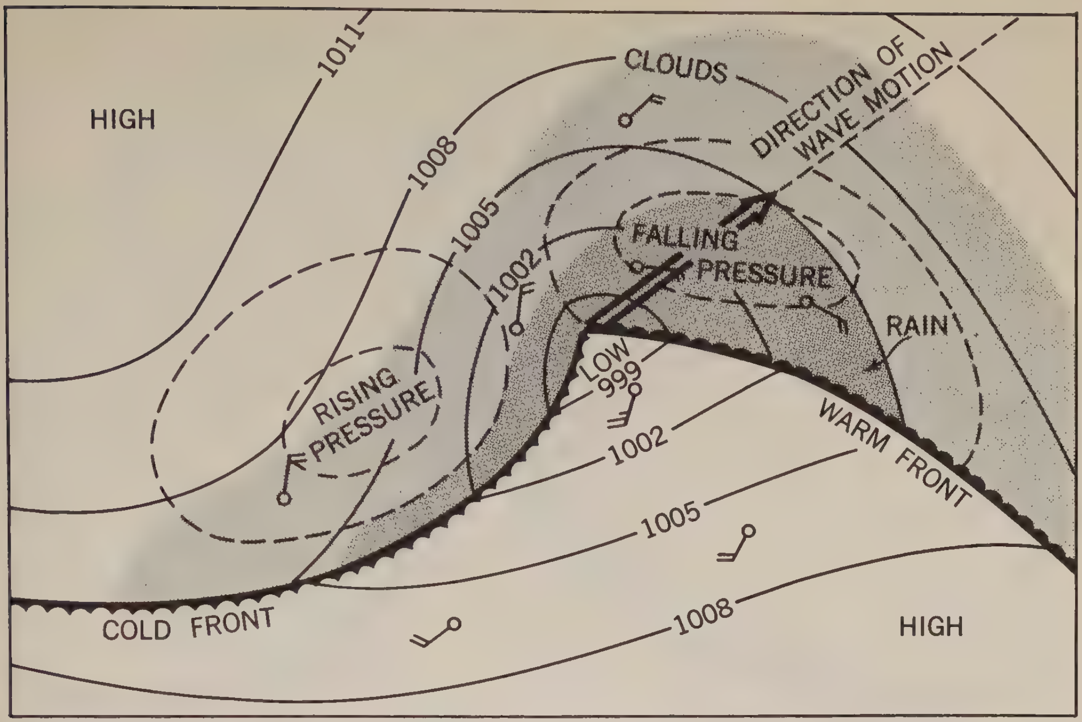

FIGURE 3812b.—A fully developed frontal wave (top view).

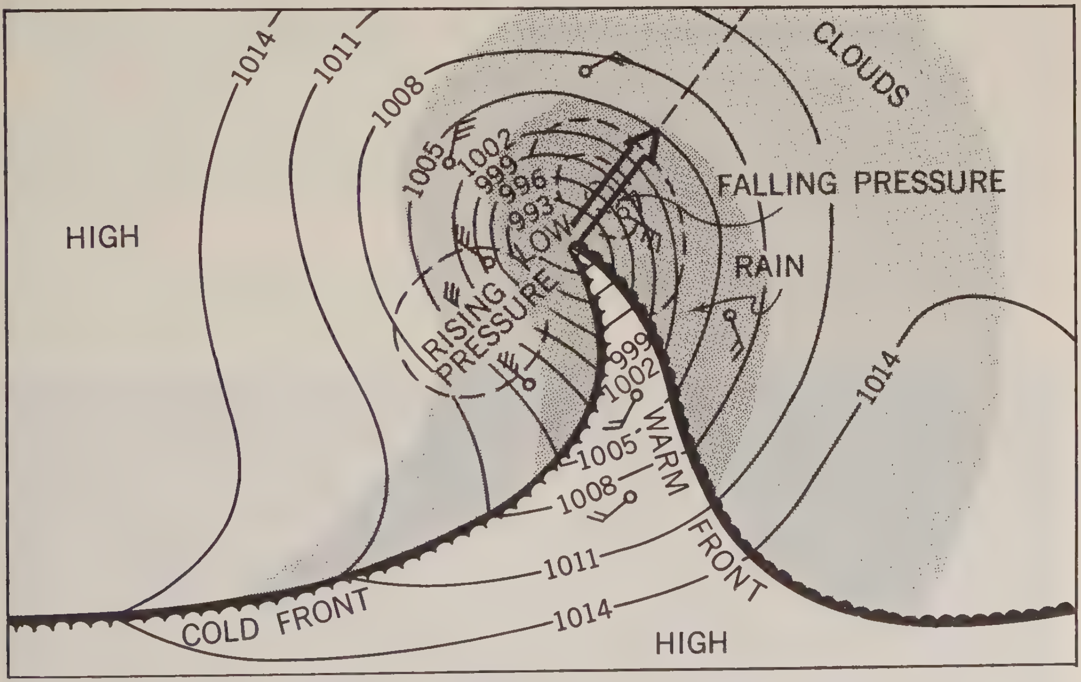

FIGURE 3812c.—A frontal wave nearing occlusion (top view).

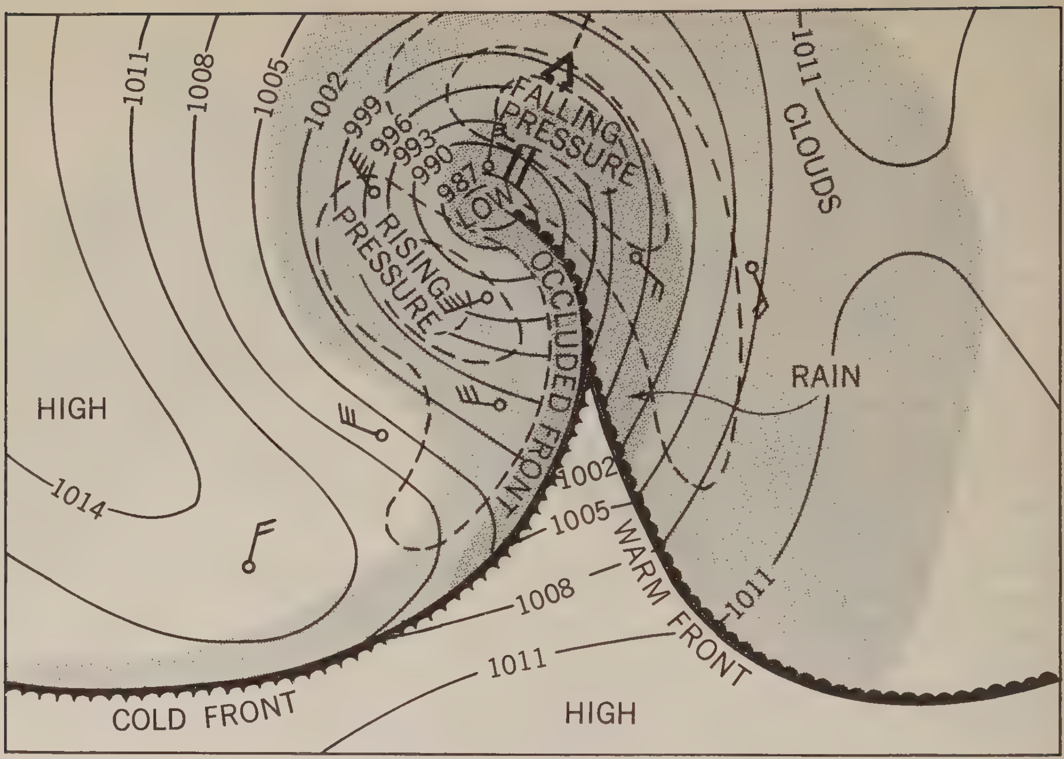

FIGURE 3812d.—An occluded front (top view).

The sequence of weather associated with a low depends greatly upon location with respect to the path of the center. That described above assumes that the observer is so located that he encounters each part of the system. If he is poleward of the path of the center of the low, the abrupt weather changes associated with the passage of fronts are not experienced. Instead, the change from the weather characteristically found ahead of a warm front to that behind a cold front takes place gradually, the exact sequence being dictated somewhat by distance from the center, as well as severity and age of the low.

Although each low follows generally the pattern given above, no two are ever exactly alike. Other centers of low pressure and high pressure and the air masses associated with them, even though they may be 1,000 miles or more away, influence

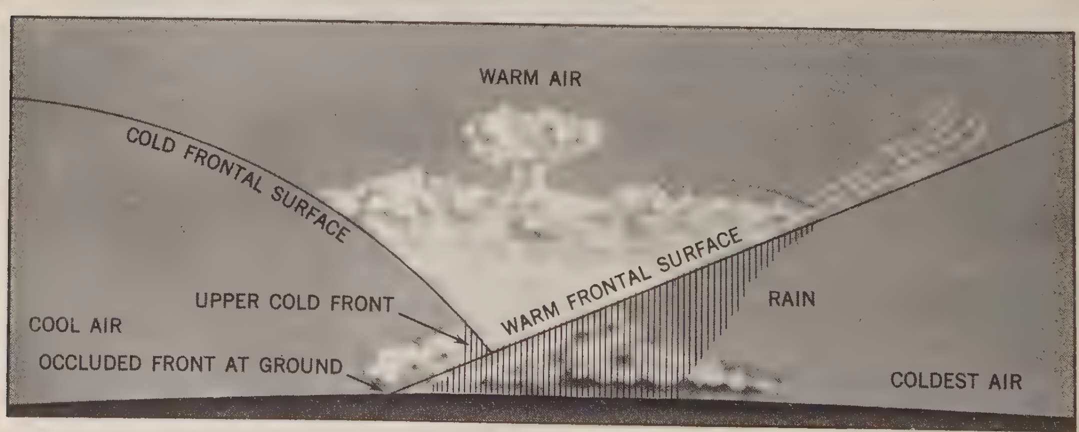

FIGURE 3812e.—An occluded front (cross section).

the formation and motion of individual low centers and their accompanying weather. Particularly, a high stalls or diverts a low. This is true of temporary highs as well as semipermanent highs.

3813. Cyclones and anticyclones.—An approximately circular portion of the atmosphere in the vicinity of a low pressure area is called a **cyclone.** A similar portion in the vicinity of an atmospheric high is called an **anticyclone.** These terms are used particularly in connection with the winds associated with such centers. Wind tends to blow from an area of high pressure to one of low pressure, but due to rotation of the earth, they are deflected toward the right in the northern hemisphere and toward the left in the southern hemisphere (art. 3804).

Because of the rotation of the earth, therefore, the circulation tends to be counterclockwise around areas of low pressure in the northern hemisphere (figs. 3812c and 3812d), and clockwise around areas of high pressure, the speed being proportional to the spacing of isobars. In the southern hemisphere, the direction of circulation is reversed. Based upon this condition, a general rule (**Buys Ballot's Law**) can be stated thus:

If an observer in the northern hemisphere faces the wind, the center of low pressure is toward his right, somewhat behind him; and the center of high pressure is toward his left and somewhat in front of him.

If an observer in the southern hemisphere faces the wind, the center of low pressure is toward his left and somewhat behind him; and the center of high pressure is toward his right and somewhat in front of him.

In a general way, these relationships apply in the case of the general distribution of pressure, as well as to temporary local pressure systems.

The reason for the wind shift along a front is that the isobars have an abrupt change of direction along these lines, as shown in figures 3812a–3812d. Since the direction of the wind is directly related to the direction of isobars, any change in the latter results in a shift in the wind direction.

In the northern hemisphere, the wind shifts toward the *right* when either a warm or cold front passes. In the southern hemisphere, the shift is toward the *left.* When the wind shifts in this direction (clockwise in the northern hemisphere and counterclockwise in the southern hemisphere), it is said to **veer.** If it shifts in the opposite direction, as when an observer is on the poleward side of the path of a frontal wave, it is said to **back.**

In an anticyclone, successive isobars are relatively far apart, resulting in light winds. In a cyclone, the isobars are more closely spaced. With a steeper pressure gradient, the winds are stronger.

Since an anticyclonic area is a region of outflowing winds, air is drawn into it from aloft. Descending air is warmed, and as air becomes warmer, its capacity for holding uncondensed moisture increases. Therefore, clouds tend to dissipate. Clear skies are characteristic of an anticyclone, although scattered clouds and showers are sometimes encountered.

In contrast, a cyclonic area is one of converging winds. The resulting upward movement of air results in cooling, a condition favorable to the formation of clouds and precipitation. More or less continuous rain and generally stormy weather are usually associated with a cyclone.

Between the two belts of high pressure associated with the horse latitudes (art. 3807), cyclones form only occasionally, generally in certain seasons, and always in certain areas at sea. These **tropical cyclones** are usually quite violent, being known under various names according to their location. They are discussed in chapter XXXIX.

In the areas of the prevailing westerlies (art. 3808), cyclones are a common occurrence, the cyclonic and anticyclonic circulation being a prominent feature of temperate latitudes. These are sometimes called **extratropical cyclones** to distinguish them from the more violent tropical cyclones. Although most of them are formed at sea, their formation over land is not unusual. As a general rule, they decrease in intensity when they encounter land, and increase when they move from the land to a water area. In their early stages, cyclones are elongated, as shown in figure 3812a, but as their life cycle proceeds, they become more nearly circular (figs. 3812b–3812d).

3814. Local winds.—In addition to the winds of the general circulation (arts. 3804–3809) and those associated with cyclones and anticyclones (art. 3813), there are numerous local winds which influence the weather in various places.

The most common of these are the **land** and **sea breezes,** caused by alternate heating and cooling of land adjacent to water. The effect is similar to that which causes the monsoons (art. 3810), but on a much smaller scale, and over shorter periods. By day the land is warmer than the water, and by night it is cooler. This effect occurs along many coasts during the summer. Between about 0900 and 1100 the temperature of the land becomes greater than that of the adjacent water. The lower levels of air over the land are warmed, and the air rises, drawing in cooler air from the sea. This is the **sea breeze.** Late in the afternoon, when the sun is low in the sky, the temperature of the two surfaces equalizes and the breeze stops. After sunset, as the land cools below the sea temperature, the air above it is also cooled. The contracting cool air becomes more dense, increasing the pressure. This results in an outflow of winds to the sea. This is the **land breeze,** which blows during the night and dies away near sunrise. Since the atmospheric pressure changes associated with this cycle are not great, the accompanying winds do not exceed gentle breezes. The circulation is generally of limited extent, reaching a distance of perhaps 20 miles inland, and not more than five or six miles offshore, and to a height of a few hundred feet. In the tropics, this process is repeated with great regularity throughout most of the year. As the latitude increases, it becomes less prominent, being masked by winds of cyclonic origin (art. 3813). However, the effect may often be present to reinforce, retard, or deflect stronger prevailing winds.

Varying conditions of topography produce a large variety of local winds throughout the world. In light airs, winds tend to follow valleys, and to be deflected from high banks and shores. Many local winds have been given distinctive names. An **anabatic wind** is one which blows up an incline, as one which blows up a hillside due to surface heating. A **katabatic wind** is one which blows down an incline due to cooling of the air. The cooler air becomes heavier than surrounding air and flows downward along the incline under the force of gravity.

A dry wind with a downward component, warm for the season, is called a **foehn.** The foehn occurs when horizontally moving air encounters a mountain barrier. As it blows upward to clear the barrier, it is cooled below the dew point, resulting in loss of moisture by cloud formation and perhaps rain. As the air continues to rise, its rate of cooling is reduced because the condensing water vapor gives off heat to the surrounding atmosphere. After crossing the mountain barrier, the air flows downward along the leeward slope, being warmed by compression as it descends to lower levels. Thus, since it loses less heat on the ascent than it gains during descent, and since it loses moisture during ascent, it arrives at the bottom of the mountains as very warm, dry air. This accounts for the warm, arid regions along the eastern side of the Rocky Mountains and in similar areas. In the Rocky Mountain region this wind is known by the name **chinook.** It may occur at any season of the year, at any hour of the day or night, and have any speed from a gentle breeze to a gale. It may last for several days, or for a very

short period. Its effect is most marked in winter, when it may cause the temperature to rise as much as 20°F to 30°F within 15 minutes, and cause snow and ice to melt within a few hours. On the west coast of the United States, the name "chinook" is given to a moist southwesterly wind from the Pacific Ocean, warm in winter and cool in summer. Cloudy weather and rain may accompany or follow this wind, which is thus quite different from the other chinook mentioned above. A foehn given the name **Santa Ana** blows through a pass and down a valley by that name in Southern California. This wind usually starts suddenly, without warning, and blows with such force that it may capsize small craft off the coast.

A cold wind blowing down an incline is called a **fall wind.** Although it is warmed somewhat during descent, as is the foehn, it is cold relative to the surrounding air. It occurs when cold air is dammed up in great quantity on the windward side of a mountain and then spills over suddenly, usually as an overwhelming surge down the other side. It is usually quite violent, sometimes reaching hurricane force. A different name for this type wind is given at each place where it is common. The **williwaw** of the Aleutian coast, the **tehuantepecer** of the Mexican and Central American coast, the **pampero** of the Argentine coast, the **mistral** of the western Mediterranean, and the **bora** of the eastern Mediterranean are examples of this type wind.

Many other local winds common to certain areas have been given distinctive names.

A **blizzard** is a violent, intensely cold wind laden with snow mostly or entirely picked up from the ground, although the term is often used popularly to refer to any heavy snowfall accompanied by strong wind. A **dust whirl** is a rotating column of air about 100 to 300 feet in height, carrying dust, leaves, and other light material. This wind, which is similar to a waterspout at sea (art. 3825), is given various local names such as **dust devil** in southwestern United States and **desert devil** in South Africa. A **gust** is a sudden, brief increase in wind speed followed by a slackening, or the violent wind or squall that accompanies a thunderstorm. A puff of wind or a light breeze affecting a small area, such as would cause patches of ripples on the surface of water, is called a **cat's paw.**

3815. Fog, like a cloud (art. 3714), is a visible assemblage of numerous tiny droplets of water, or ice crystals, formed by condensation of water vapor in the air. However, the base of a cloud is above the surface of the earth, while fog is in contact with the surface.

Radiation fog forms over low-lying land on clear, calm nights. As the land radiates heat and becomes cooler, it cools the air immediately above the surface. This causes a **temperature inversion** to form, the temperature for some distance upward *increasing* with height. If the air is cooled to its dew point (art. 3713), fog forms. Often, cooler and more dense air drains down surrounding slopes to heighten the effect. Radiation fog is often quite shallow, and is usually thickest at the surface. After sunrise the fog may "lift," as shown in figure 3815, and gradually dissipate, usually being entirely gone by noon. At sea the temperature of the water undergoes little change between day and night, and so radiation fog is seldom encountered more than ten miles from shore.

Advection fog forms when warm, moist air blows over a colder surface and is cooled below its dew point. This type, most commonly encountered at sea, may be quite thick and often persists over relatively long periods. The maximum density might be at nearly any height. Advection fog is common over cold ocean currents. If the wind is strong enough to thoroughly mix the air, condensation may take place at some distance above the surface of the earth, forming low stratus clouds (art. 3714) rather than fog.

Off the coast of California, winds create an offshore current which displaces the warm surface water, causing an upwelling of colder water. Moist air being transported along the coast in the same wind system is cooled, and advection fog results. In the coastal valleys, fog is sometimes formed when moist air blown inland during the afternoon is cooled by radiation during the night. Both of these are called **California fog** because they are peculiar to California and its coastal valleys.

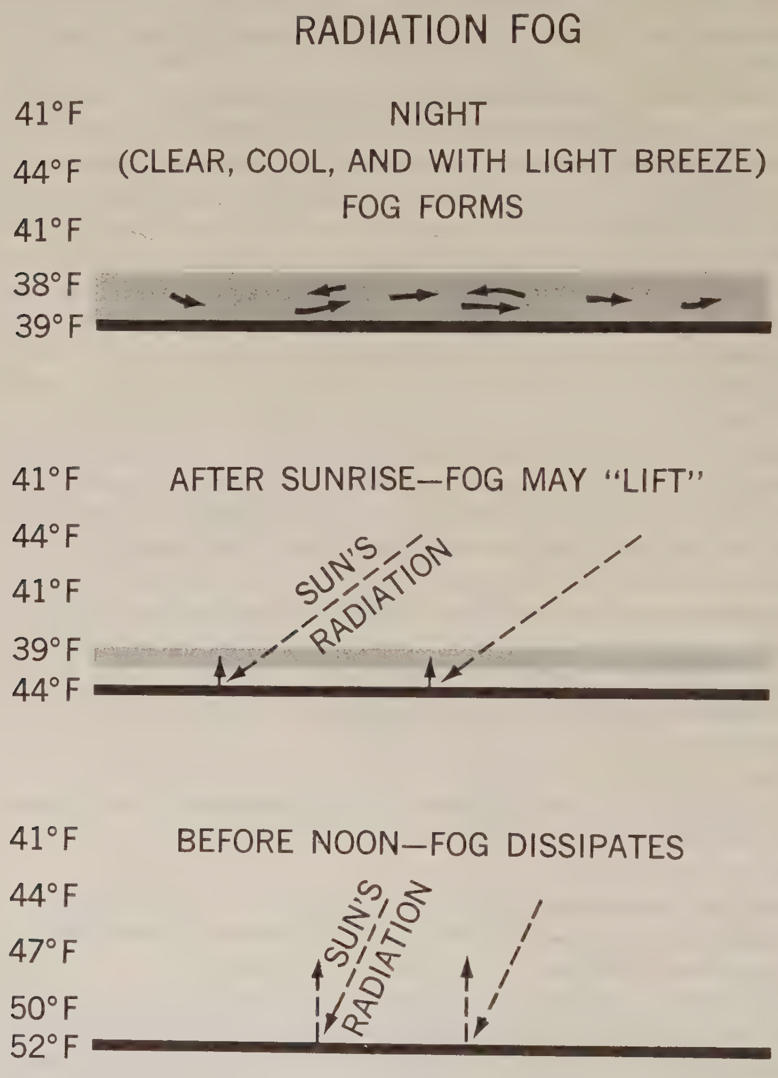

FIGURE 3815.—Formation and dissipation of radiation fog.

When very cold air moves over warmer water, wisps of visible water vapor may rise from the surface as the water "steams," as shown in figure 2505. In extreme cases this **frost smoke,** or **arctic sea smoke,** may rise to a height of several hundred feet, the portion near the surface constituting a dense fog which obscures the horizon and surface objects, but usually leaves the sky relatively clear.

Fog consisting of ice crystals is called **ice fog,** or **pogonip** by Western American Indians. Thin fog of relatively large particles, or very fine rain lighter than drizzle, is called **mist.** A mixture of smoke and fog is called **smog.**

Haze consists of fine dust or salt particles in the air, too small to be individually apparent, but in sufficient number to reduce horizontal visibility and cast a bluish or yellowish veil over the landscape, subduing its colors and making objects appear indistinct. This is sometimes called **dry haze** to distinguish it from **damp haze,** which consists of small water droplets or moist particles in the air, smaller and more scattered than light fog. In international meteorological practice, the term "haze" is used to refer to a condition of atmospheric obscurity caused by dust and smoke.

3816. Mirage.—As explained in article 1613, light is refracted as it passes through the atmosphere. When refraction is normal, objects appear slightly elevated, and the visible horizon is farther from the observer than it otherwise would be. Since the effects are uniformly progressive, they are not apparent to the observer. When refraction is not normal, some form of **mirage** may occur. A mirage is an optical phenomenon in which objects appear distorted, displaced (raised or lowered), magnified, multiplied, or inverted due to varying atmospheric refraction which occurs when a layer of air near the earth's surface differs greatly in density from surrounding air. This may occur when there is a rapid and sometimes irregular change of temperature or humidity with height.

If there is a temperature inversion (increase of temperature with height), particularly if accompanied by a rapid decrease in humidity, the refraction is greater than normal. Objects appear elevated, and the visible horizon is farther away. Objects which are normally below the horizon become visible. This is called **looming.** If the upper portion of an object is raised much more than the bottom part, the object appears taller than usual, an effect called **towering.** If the lower part of an object is raised more than the upper part, the object appears shorter, an effect called **stooping.** When the refraction is greater than normal, a **superior mirage** may occur. An inverted image is seen above the object, and sometimes an erect image appears over the inverted one, with the bases of the two images touching. Greater than normal refraction usually occurs when the water is much colder than the air above it.

If the temperature decrease with height is much greater than normal, refraction is less than normal, or may even cause bending in the opposite direction. Objects appear lower than normal, and the visible horizon is closer to the observer. This is called **sinking.** Towering or stooping may occur if conditions are suitable. When the refraction is reversed, an **inferior mirage** may occur. A ship or an island appears to be floating in the air above a shimmering horizon, possibly with an inverted image beneath it. Conditions suitable to the formation of an inferior mirage occur when the surface is much warmer than the air above it. This usually requires a heated land mass, and therefore is more common near the coast than at sea.

When refraction is not uniformly progressive, objects may appear distorted, taking an almost endless variety of shapes. The sun when near the horizon is one of the objects most noticeably affected. A **fata morgana** is a complex mirage characterized by marked distortion, generally in the vertical. It may cause objects to appear towering, magnified, and at times even multiplied.

3817. Sky coloring.—White light is composed of light of all colors. Color is related to wave length, the visible spectrum varying from about 0.000038 to 0.000076 centimeters (art. 1003). The characteristics of each color are related to its wave length (or frequency). Thus, the shorter the wave length, the greater the amount of bending when light is refracted. It is this principle that permits the separation of light from celestial bodies into a **spectrum** ranging from red, through orange, yellow, green, and blue, to violet, with long-wave infrared (black light) being slightly outside the visible range at one end and short-wave ultraviolet being slightly outside the visible

range at the other end. Light of shorter wave length is scattered and diffracted more than that of longer wave length.

Light from the sun and moon is white, containing all colors. As it enters the earth's atmosphere, a certain amount of it is scattered. The blue and violet, being of shorter wave length than other colors, are scattered most. Most of the violet light is absorbed in the atmosphere. Thus, the scattered blue light is most apparent, and the sky appears blue. At great heights, above most of the atmosphere, it appears black.

When the sun is near the horizon, its light passes through more of the atmosphere than when higher in the sky, resulting in greater scattering and absorption of blue and green light, so that a larger percentage of the red and orange light penetrates to the observer. For this reason the sun and moon appear redder at this time, and when this light falls upon clouds, they appear colored. This accounts for the colors at sunset and sunrise. As the setting sun approaches the horizon, the sunset colors first appear as faint tints of yellow and orange. As the sun continues to set, the colors deepen. Contrasts occur, due principally to difference in height of clouds. As the sun sets, the clouds become a deeper red, first the lower clouds and then the higher ones, and finally they fade to a gray.

When there is a large quantity of smoke, dust, or other material in the sky, unusual effects may be observed. If the material in the atmosphere is of suitable substance and quantity to absorb the longer wave red, orange, and yellow radiations, the sky may have a greenish tint, and even the sun or moon may appear green. If the green light, too, is absorbed, the sun or moon may appear blue. A **green moon** or **blue moon** is most likely to occur when the sun is slightly below the horizon and the longer wave length light from the sun is absorbed, resulting in green or blue light being cast upon the atmosphere in front of the moon. The effect is most apparent if the moon is on the same side of the sky as the sun.

3818. Rainbows.—The familiar arc of concentric colored bands seen when the sun shines on rain, mist, spray, etc., is caused by refraction, internal reflection, and diffraction of sunlight by the drops of water. The center of the arc is a point 180° from the sun, in the direction of a line from the sun, through the observer. The radius of the brightest rainbow is 42°. The colors are visible because of the difference in the amount of refraction of the different colors making up white light, the light being spread out to form a spectrum (art. 3817). Red is on the outer side and blue and violet on the inner side, with orange, yellow, and green between, in that order from red.

Sometimes a secondary rainbow is seen outside the primary one, at a radius of about 50°. The order of colors of this rainbow is reversed. On rare occasions a faint rainbow is seen on the same side as the sun. The radius of this rainbow and the order of colors are the same as those of the primary rainbow.

A similar arc formed by light from the moon (a lunar rainbow) is called a **moonbow.** The colors are usually very faint. A faint, white arc of about 39° radius is occasionally seen in fog opposite the sun. This is called a **fogbow,** although its origin is controversial, some considering it a halo (art. 3819).

3819. Halos.—Refraction, or a combination of refraction and reflection, of light by ice crystals in the atmosphere (cirrostratus clouds, art. 3714) may cause a **halo** to appear. The most common form is a ring of light of radius 22° or 46° with the sun or moon at the center. Occasionally a faint, white circle with a radius of 90° appears around the sun. This is called a **Hevelian halo.** It is probably caused by refraction and internal reflection of the sun's light by bipyramidal ice crystals. A halo formed by refraction is usually faintly colored like a rainbow (art. 3818), with red nearest the celestial body, and blue farthest from it.

A brilliant rainbow-colored arc of about a quarter of a circle with its center at the zenith, and the bottom of the arc about 46° above the sun, is called a **circumzenithal arc.** Red is on the outside of the arc, nearest the sun. It is produced by the refraction and dispersion of the sun's light striking the top of prismatic ice crystals in the atmosphere. It usually lasts for only about five minutes, but may be so brilliant as to be mistaken for an unusually bright rainbow. A similar arc formed 46° *below* the sun, with red on the upper side, is called a **circumhorizontal arc.** Any arc tangent to a heliocentric halo (one surrounding the sun) is called a **tangent arc.** As the sun increases in elevation, such arcs tangent to the halo of 22° gradually bend their ends toward each other. If they meet, the elongated curve enclosing the circular halo is called a **circumscribed halo.** The inner edge is red.

A halo consisting of a faint, white circle through the sun and parallel to the horizon is called a **parhelic circle.** A similar one through the moon is called a **paraselenic circle.** They are produced by reflection of sunlight or moonlight from vertical faces of ice crystals.

A **parhelion** (plural *parhelia*) is a form of halo consisting of an image of the sun at the same altitude and some distance from it, usually 22°, but occasionally 46°. A similar phenomenon occurring at an angular distance of 120° (sometimes 90° or 140°) from the sun is called a **paranthelion.** One at an angular distance of 180°, a rare occurrence, is called an **anthelion,** although this term is also used to refer to a luminous, colored ring or **glory** sometimes seen around the shadow of one's head on a cloud or fog bank. A parhelion is popularly called a **mock sun** or **sun dog.** Similar phenomena in relation to the moon are called **paraselene** (popularly a **mock moon** or **moon dog**), **parantiselene,** and **antiselene.** The term *parhelion* should not be confused with *perihelion,* that orbital point nearest the sun when the sun is the center of attraction (art. 1407).

A **sun pillar** is a glittering shaft of white or reddish light occasionally seen extending above and below the sun, usually when the sun is near the horizon. A phenomenon similar to a sun pillar, but observed in connection with the moon, is called a **moon pillar.** A rare form of halo in which horizontal and vertical shafts of light intersect at the sun is called a **sun cross.** It is probably due to the simultaneous occurrence of a sun pillar and a parhelic circle.

3820. Corona.—When the sun or moon is seen through altostratus clouds (art. 3714), its outline is indistinct, and it appears surrounded by a glow of light called a **corona.** This is somewhat similar in appearance to the corona seen around the sun during a solar eclipse (art. 1424). When the effect is due to clouds, however, the glow may be accompanied by one or more rainbow-colored rings of small radii, with the celestial body at the center. These can be distinguished from a halo by their much smaller radii and also by the fact that the order of the colors is reversed, red being on the inside, nearest the body, in the case of the halo, and on the outside, away from the body, in the case of the corona.

A corona is caused by diffraction of light by tiny droplets of water. The radius of a corona is inversely proportional to the size of the water droplets. A large corona indicates small droplets. If a corona decreases in size, the water droplets are becoming larger and the air more humid. This may be an indication of an approaching rainstorm.

The glow portion of a corona is called an **aureole.**

3821. The green flash.—As light from the sun passes through the atmosphere, it is refracted. Since the amount of bending is slightly different for each color, separate images of the sun are formed in each color of the spectrum. The effect is similar to that

of imperfect color printing in which the various colors are slightly out of register. However, the difference is so slight that the effect is not usually noticeable. At the horizon, where refraction is maximum, the greatest difference, which occurs between violet at one end of the spectrum and red at the other, is about ten seconds of arc. At latitudes of the United States, about 0.7 second of time is needed for the sun to change altitude by this amount when it is near the horizon. The red image, being bent least by refraction, is first to set and last to rise. The shorter wave blue and violet colors are scattered most by the atmosphere, giving it its characteristic blue color (art. 3817). Thus, as the sun sets, the green image may be the last of the colored images to drop out of sight. If the red, orange, and yellow images are below the horizon, and the blue and violet light is scattered and absorbed, the upper rim of the green image is the only part seen, and the sun appears green. This is the **green flash.** The shade of green varies, and occasionally the blue image is seen, either separately or following the green flash (at sunset). On rare occasions the violet image is also seen. These colors may also be seen at sunrise, but in reverse order. They are occasionally seen when the sun disappears behind a cloud or other obstruction.

The phenomenon is not observed at each sunrise or sunset, but under suitable conditions is far more common than generally supposed. Conditions favorable to observation of the green flash are a sharp horizon, clear atmosphere, a temperature inversion (art. 3815), and an attentive observer. Since these conditions are more frequently met when the horizon is formed by the sea than by land, the phenomenon is more common at sea. With a sharp sea horizon and clear atmosphere, an attentive observer may see the green flash at as many as 50 percent of sunsets and sunrises, although a telescope may be needed for some of the observations.

Duration of the green flash (including the time of blue and violet flashes) of as long as ten seconds has been reported, but such length is rare. Usually it lasts for a period of about half a second to two and one-half seconds with about one and a quarter seconds being average. This variability is probably due primarily to changes in the index of refraction (art. 1613) of the air near the horizon.

Under favorable conditions, a momentary green flash has been observed at the setting of Venus and Jupiter. A telescope improves the chances of seeing such a flash from a planet, but is not a necessity.

3822. Crepuscular rays are beams of light from the sun passing through openings in the clouds, and made visible by illumination of dust in the atmosphere along their paths. Actually, the rays are virtually parallel, but because of perspective appear to diverge. Those appearing to extend downward are popularly called **backstays of the sun,** or **sun drawing water.** Those extending upward and across the sky, appearing to converge toward a point 180° from the sun, are called **anticrepuscular rays.**

3823. The atmosphere and radio waves.—Radio waves traveling through the atmosphere exhibit many of the properties of light, being refracted, reflected, diffracted, and scattered. These and other effects are discussed in chapter X.

3824. Atmospheric electricity.—Various conditions induce the formation of electrical charges in the atmosphere. When this occurs, there is often a difference of electron charge between various parts of the atmosphere, and between the atmosphere and earth or terrestrial objects. When this difference exceeds a certain minimum value depending upon the conditions, the static electricity is discharged, resulting in phenomena such as lightning or St. Elmo's fire.

Lightning is the discharge of electricity from one part of a thundercloud (art. 3714) to another, from one such cloud to another, or between such a cloud and the earth or a terrestrial object.

Enormous electrical stresses build up within thunderclouds and between such clouds and the earth. At some point the resistance of the intervening air is overcome. At first the process is a progressive one, probably starting as a brush discharge (St. Elmo's fire) and growing by ionization. The breakdown follows an irregular path along the line of least resistance. A hundred or more individual discharges may be necessary to complete the path between points of opposite polarity. When this "leader stroke" reaches its destination, a heavy "main stroke" immediately follows in the opposite direction. This main stroke is the visible lightning, which may be tinted any color, depending upon the nature of the gases through which it passes. The illumination is due to the high degree of ionization of the air, which causes many of the atoms to be in excited states and emit radiation.

Thunder, the noise that often accompanies lightning, is caused by the heating and ionizing of the air by lightning, which results in rapid expansion of the air along its path and the sending out of a compression wave. Thunder may be heard at a distance of as much as 15 miles, but generally does not carry that far. The elapsed time between the flash of lightning and reception of the accompanying sound of thunder is an indication of the distance, because of the difference in travel time of light and sound. Since the former is comparatively instantaneous, and the speed of sound is about 1,117 feet per second, the approximate distance in nautical miles is equal to the elapsed time in seconds, divided by 5.5. If there is no accompanying thunder, the flash is called **heat lightning.**

St. Elmo's fire is a luminous discharge of electricity from pointed objects such as the masts and yardarms of ships, lightning rods, steeples, mountain tops, blades of grass, human hair, arms, etc., when there is a considerable difference in the electrical charge between the object and the air. It appears most frequently during a storm. An object from which St. Elmo's fire emanates is in danger of being struck by lightning, since this type discharge may be the initial phase of the leader stroke. Throughout history those who have not understood St. Elmo's fire have regarded it with superstitious awe, considering it a supernatural manifestation. This view is reflected in the name **corposant** (from "corpo santo," meaning "body of a saint") sometimes given this phenomenon.

The **aurora** is a luminous glow appearing in varied forms in the thin atmosphere high above the earth, due to radiation from the sun. This phenomenon is discussed in article 2526.

3825. Waterspouts.—A waterspout is a small, whirling storm over the ocean or inland waters. Its chief characteristic is a funnel-shaped cloud extending, in a fully developed spout, from the surface of the water to the base of a cumulus type cloud (fig. 3825). The water in a spout is mostly confined to its lower portion, and may be either salt spray drawn up by the sea surface, or fresh water resulting from condensation due to the lowered pressure in the center of the vortex creating the spout. Waterspouts usually rotate in the same direction as cyclones (counterclockwise in the northern hemisphere and clockwise in the southern hemisphere), but the opposite rotation is occasionally observed. They are found most frequently in tropical regions, but are not uncommon in higher latitudes.

Waterspouts may be divided into two classes, according to their different origins and appearances. In the true waterspout, the vortex is formed in clouds by the interaction of air currents flowing in opposite directions. This type occurs mainly in the vicinity of a squall line (art. 3812). A similar disturbance over land is called a **tornado.** The second type, which may be considered a pseudo waterspout, originates just above the water surface, in unstable air, and builds upward, frequently under clear skies.

FIGURE 3825.—Waterspouts.

This type is identical to the whirling pillars of sand and dust often seen on deserts (art. 3814) and usually occurs only over very warm water surfaces.

Waterspouts vary in diameter from a few feet to several hundred feet, and in height from a few hundred feet to several thousand feet. Sometimes they assume fantastic shapes and may even seem to coil about themselves. Since a waterspout is often inclined to the vertical, its actual length may be much greater than indicated by its height. The highest waterspout on record was one of 5,014 feet observed near New South Wales, Australia, on May 16, 1898.

3826. Deck ice.—Ships traveling through regions where the air temperature is below freezing may acquire thick deposits of ice as a result of salt spray freezing on

the rigging or deck areas (fig. 3826). Also, precipitation may freeze to the superstructure and exposed areas of the vessel, increasing the load of ice.

On small vessels in heavy seas and freezing weather, deck ice may accumulate very rapidly and increase the topside weight to such an extent as to reduce seriously the stability of the vessel.

3827. Forecasting weather.—The prediction of weather at some future time is based upon an understanding of weather processes, and observations of present conditions. Thus, one learns that when there is a certain sequence of cloud types (art. 3714), rain can usually be expected to follow within a certain period. If the sky is cloudless, more heat will be received from the sun by day, and more heat will be radiated outward from the warm earth by night than if the sky is overcast. If the wind is in such a direction that warm, moist air will be transported to a colder surface, fog can be

FIGURE 3826.—Deck ice.

expected. A falling barometer indicates the approach of a "low," probably accompanied by stormy weather. Thus, before the science of meteorology was developed, many individuals learned to interpret certain phenomena in terms of future weather, and to make reasonably accurate forecasts for short periods into the future.

With the establishment of weather observation stations, additional information became available. As such observations expanded, and communication facilities improved, knowledge of simultaneous conditions over wider areas became available. This made possible the collection of these "synoptic" reports at civilian forecast centers and Navy Fleet Weather Centrals.

The individual observations are made at government-operated stations on shore, and aboard vessels at sea. Observations aboard merchant ships at sea are made and transmitted on a voluntary and cooperative basis. The various national meteorological services supply shipmasters with blank forms, printed instructions, and other materials essential to the making, recording, and interpreting of observations. Any shipmaster can render a particularly valuable service by reporting all contacts with tropical cyclones (ch. XXXIX).

Symbols and numbers are used to indicate on a **synoptic chart,** popularly called a **weather map,** the conditions at each observation station. Isobars are drawn through lines of equal atmospheric pressure, fronts are located and marked by symbol (fig. 3827), areas of precipitation and fog are indicated, etc.

Ordinarily, surface charts are prepared every six hours, but at a few centers they are drawn every three hours. In addition, synoptic charts for selected heights are

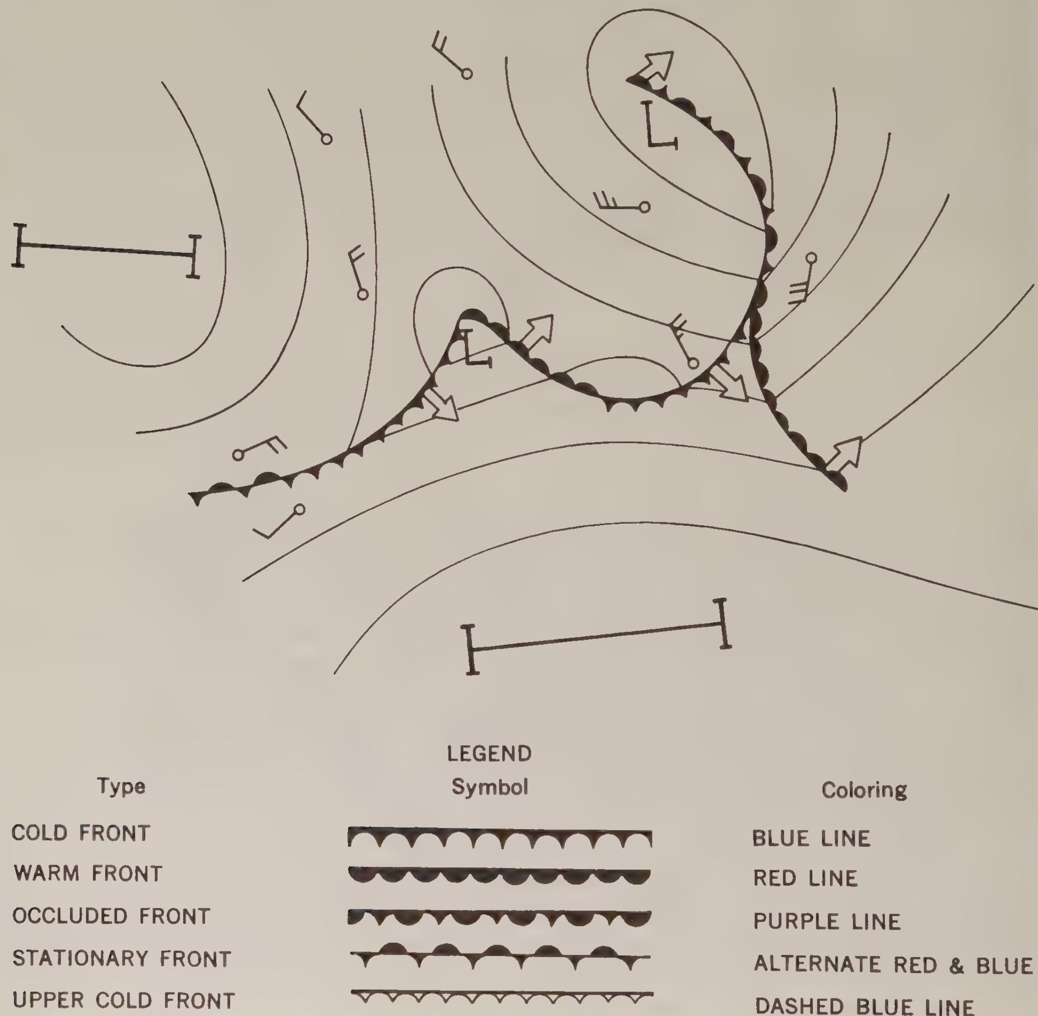

FIGURE 3827.—Designation of fronts on weather maps.

prepared two to four times per day. Knowledge of conditions aloft is of value in establishing the three-dimensional structure of the atmosphere at any time, and the motions upon which forecasts are based.

By studying the latest synoptic weather chart and comparing it with previous charts, a trained meteorologist having a knowledge of local weather peculiarities can draw certain inferences regarding future weather, and issue a forecast. Weather forecasts are essentially a form of extrapolation (art. P6). Past changes and present trends are used to predict future events. In areas where certain sequences follow with great certainty, the probability of an accurate forecast is very high. In transitional areas, or areas where an inadequate number of synoptic reports is available, the fore-

casts are less reliable. Forecasts, then, are based upon the principles of probability (ch. XXIX), and where nature provides low probability, high reliability should not be expected. In any area, the probability of a given event occurring decreases with the lead time. Thus, a forecast for six hours after a synoptic chart is drawn should be more reliable than one for 24 hours ahead. Long-term forecasts for two weeks or a month in advance are limited to general statements. For example, a prediction is made as to which areas will have temperatures above or below normal, and how precipitation will compare with normal, but no attempt is made to state that rainfall will occur at a certain time and place.

Forecasts are issued for various areas. The national meteorological services of most maritime nations, including the United States, issue forecasts for ocean areas and warnings of the approach of storms. The efforts of the various nations are coordinated through the World Meteorological Organization.

3828. Dissemination of weather information is carried out in a number of ways. Forecasts are widely broadcast by commercial and government radio stations, and printed in newspapers. Shipping authorities on land are kept informed by telegraph and telephone. Visual storm warnings are displayed in various ports, and storm warnings are broadcast by radio.

Through the use of codes, a simplified version of synoptic weather charts is transmitted to various stations ashore and afloat. Rapid transmission of completed maps has been made possible by the development of facsimile transmitters and receivers. This system is based upon detailed scanning, by a photoelectric detector, of properly illuminated black and white copy. The varying degrees of light intensity are converted to electric energy which is transmitted to the receiver and converted back to a black and white presentation.

Complete information on dissemination of weather information by radio is given in H.O. Pubs. Nos. 118–A and 118–B, *Radio Weather Aids*. This publication lists broadcast schedules and weather codes. Information on day and night visual storm warnings is given in the various volumes of sailing directions and coast pilots.

3829. Interpreting the weather.—The factors which determine weather are numerous and varied. Ever-increasing knowledge regarding them makes possible a continually improving weather service. However, the ability to forecast is acquired through study and long practice, and therefore the services of a trained meteorologist should be utilized whenever available.

The value of a forecast is increased if one has access to the information upon which it is based, and understands the principles and processes involved. It is sometimes as important to know the various types of weather that *might* be experienced as it is to know which of several possibilities is *most likely* to occur.

At sea, reporting stations are unevenly distributed, sometimes leaving relatively large areas with incomplete reports, or none at all. Under these conditions, the locations of highs, lows, fronts, etc., are imperfectly known, and their very existence may even be in doubt. At such times the mariner who can interpret the observations made from his own vessel may be able to predict weather during the next 24 hours more reliably than a trained meteorologist some distance away with incomplete information.

Knowledge of the various relationships given in chapters XXXVII, XXXVIII, and XXXIX is of value, but only the more elementary principles are presented. Further information can be obtained from meteorological publications such as those listed at the ends of the weather chapters. The information obtained from these references will provide a background for proper interpretation of individual experience. If one uses every opportunity to observe and interpret weather sequences, he can develop knowledge and skill that will serve as a valuable supplement to information

given in weather broadcasts, or to supply information for areas not covered by such broadcasts.

3830. Influencing the weather.—Meteorological activities are devoted primarily to understanding weather processes, and predicting future weather. However, as knowledge regarding cause-and-effect relationships increases, the possibility of being able to induce certain results by artificially producing the necessary conditions becomes greater. The most promising results to date have been in the encouraging of precipitation by "seeding" supercooled clouds with powdered dry ice or silver iodide smoke. The effectiveness of this procedure is controversial. Various methods of decreasing the intensity of tropical cyclones, or of diverting their courses, have been suggested, but a satisfactory method has not been devised.

If a way is found to influence weather on a major scale, legal and possibly moral problems will be created due to conflicting interests.

CHAPTER XXXIX

TROPICAL CYCLONES

3901. Introduction.—A **tropical cyclone** is a violent cyclone (art. 3813) originating in the tropics. Although it generally resembles the extratropical cyclone originating in higher latitudes, there are important differences, the principal one being the concentration of a large amount of energy into a relatively small area. Tropical cyclones are infrequent in comparison with middle- and high-latitude storms, but they have a record of destruction far exceeding that of any other type of storm. Because of their fury, and the fact that they are predominantly oceanic, they merit the special attention of all mariners, whether professional or amateur.

Rarely does the mariner who has experienced a fully developed tropical cyclone at sea wish to encounter a second one. He has learned the wisdom of avoiding them if possible. The uninitiated may be misled by the deceptively small size of a tropical cyclone as it appears on a weather map, and by the fine weather experienced only a few hundred miles from the reported center of such a storm. The rapidity with which the weather can deteriorate with approach of the storm, and the violence of the fully developed tropical cyclone, are difficult to visualize if they have not been experienced.

3902. Areas of occurrence.—Tropical cyclones occur almost entirely in six rather distinct regions, four in the northern hemisphere and two in the southern hemisphere, as shown in figure 3902. The name by which such a disturbance is commonly known varies somewhat with the locality, as follows:

Region I. North Atlantic (West Indies, Caribbean Sea, Gulf of Mexico, and waters off the East Coast of the United States). A tropical cyclone with winds of 64 knots or greater is called a **hurricane.**

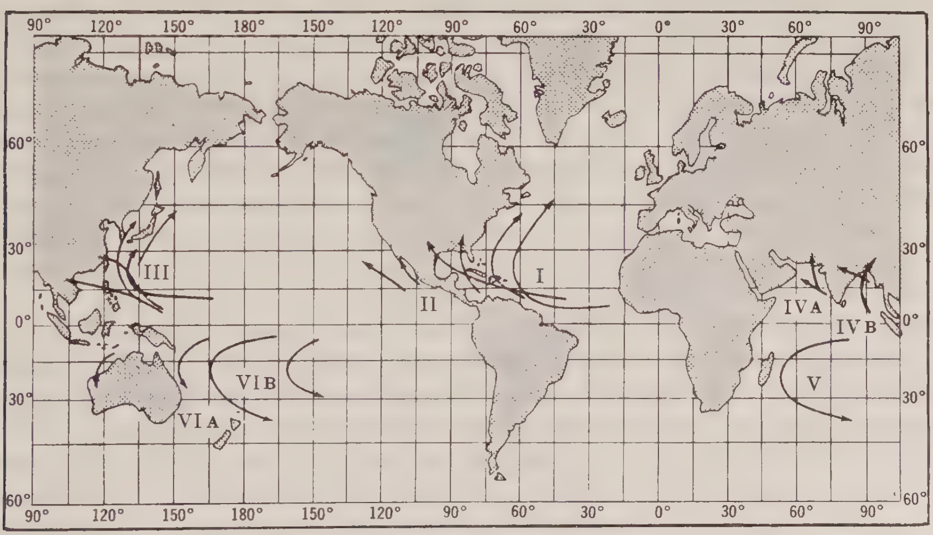

FIGURE 3902.—Areas in which tropical cyclones occur, and their approximate tracks.

Region II. Southeastern North Pacific (waters off west coast of Mexico and Central America). The name **hurricane** is applied, as in Region I.

Region III. Far East (the entire area west of the Mariana and Caroline Islands, across the Philippines and the China Sea, and northeastward to China and Japan). A fully developed storm with winds of 60 knots or greater is called a **typhoon** or, locally in the Philippine Islands, a **baguio.**

Region IV. *A.* Arabian Sea. *B.* Bay of Bengal. In these areas the storms are called **cyclones.**

Region V. South Indian Ocean (in the vicinity and to the east of Madagascar). As in Region IV, the tropical cyclone is called a **cyclone.**

Region VI. *A.* Australian waters (to longitude 160° E). *B.* South Pacific (the western portion, east of longitude 160° E). Several names are applied in this area, **cyclone** being the most common. One originating in the Timor Sea and moving southwest and then southeast across the interior of northwestern Australia is called a **willy-willy.** One to the east of Australia may be called a **hurricane.**

The only tropical ocean area in which tropical cyclones have not been encountered at some time is the South Atlantic.

As a tropical cyclone moves out of the tropics to higher latitudes, it normally loses energy slowly, expanding in area until it gradually dissipates or acquires the characteristics of extratropical cyclones. At any stage, a tropical cyclone normally loses energy at a much faster rate if it moves over land.

3903. Season and frequency of occurrence.—In Region III tropical cyclones may be encountered in any month of the year, though less frequently in winter than in summer. In the other regions, they occur only in the summer or autumn of that area, as shown in figure 3903. The total number for the northern hemisphere reaches a sharp peak in September. In general, this is the month of greatest frequency in each of the first four regions, although the Far East reaches its maximum in August, and in the Arabian Sea there are two peaks, one in June, and the other in late October. In the southern hemisphere, the maximum number is not as sharply peaked, being distributed nearly equally over January, February, and March, the summer season of that hemisphere.

The occurrence of tropical cyclones in an area is not as regular as might be inferred from a curve such as any of those of figure 3903, which are averages over a great many years. Even near the peak of a tropical cyclone season in any area there are periods when no tropical storms are observed. At the other extreme, as many as three hurricanes have been in progress at the same time in the North Atlantic, and as many as four typhoons in the Far East. The *average* total number of tropical cyclones occurring per year is 43 in the Northern Hemisphere and 13 in the Southern Hemisphere, or 56 throughout the world. However, the actual number in an area varies greatly from year to year. In the North Atlantic, where the greatest irregularity occurs, there have been as few as two and as many as 21 in a year, although the average number is seven. In the Far East, the number has varied from 13 to 25.

3904. Storm tracks.—Tropical cyclones form over the ocean, in low latitudes. As one forms, it drifts slowly westward with the current of free air in which it forms. As it reaches the edge of a subtropical anticyclone, the storm, together with the general mass of air, drifts farther from the equator, in many instances curving poleward and then eastward with the winds of the general circulation (art. 3804). In general, a tropical cyclone moves very slowly at first, its speed varying from about five to 20 knots. The speed gradually increases as the storm progresses, and may, in a few instances, reach a value of 50 knots or more when the storm reaches temperate latitudes.

The average track varies somewhat as the season progresses, and individual storm tracks may differ widely from the average. Region I, the North Atlantic, is typical of the changes. In August, about 80 percent originate in the southern North Atlantic and the eastern Caribbean, and about 20 percent in the western Caribbean and Gulf of Mexico. About 60 percent curve toward the right, roughly paralleling the coast of North America, and about 40 percent continue on westward, as shown in figure 3904a.

By the peak of the season, in September, the number forming in the southern North Atlantic and eastern Caribbean has dropped to 70 percent, but the number curving to-

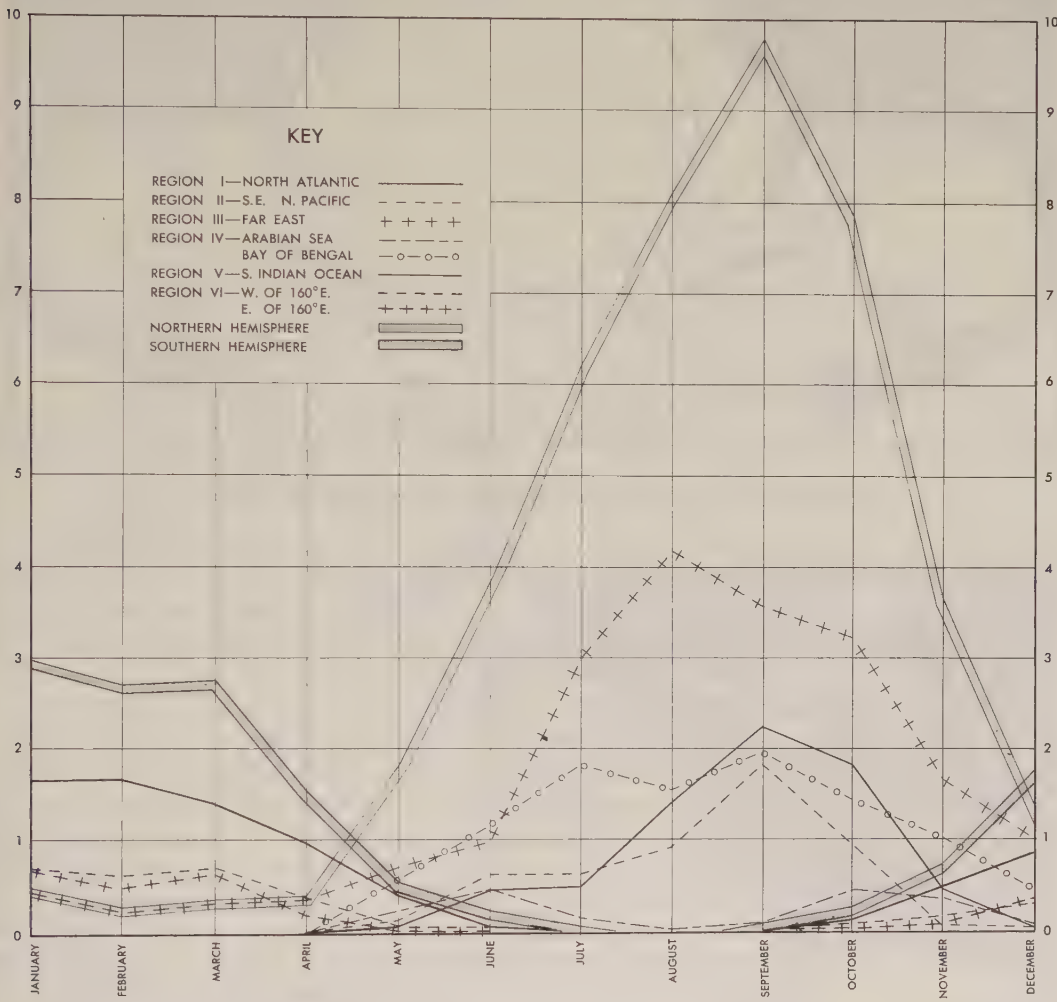

FIGURE 3903.—Average number of tropical disturbances per month in the various regions.

ward the right has increased to about the same percentage. The normal track has moved a little farther offshore in the lower latitudes, but has straightened somewhat so as to pass over eastern Newfoundland. This is shown in figure 3904b.

By October, the number originating in the southern North Atlantic and eastern Caribbean has dropped to 50 percent; and 80 percent of them curve, but at a point farther west, and more sharply, as shown in figure 3904c. By November, the change has been somewhat back toward the condition in September. As the season progresses, the deviation from average becomes greater and more common.

FIGURE 3904a.—Average North Atlantic storm tracks in August.

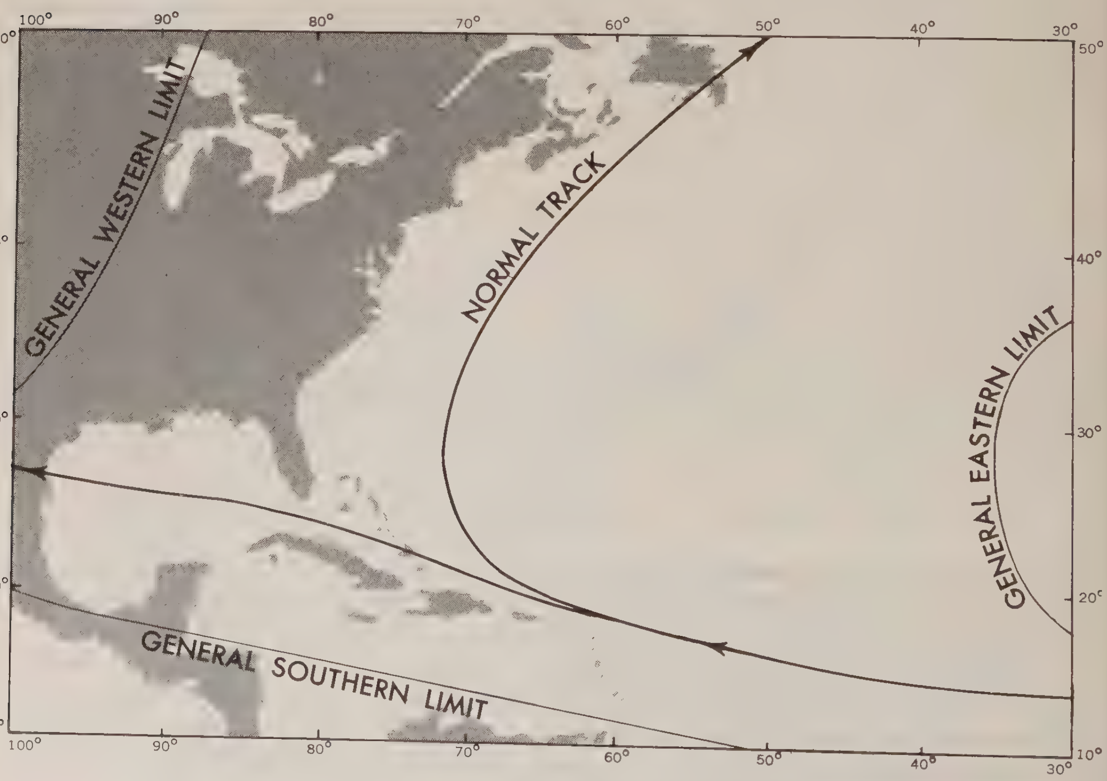

FIGURE 3904b.—Average North Atlantic storm tracks in September.

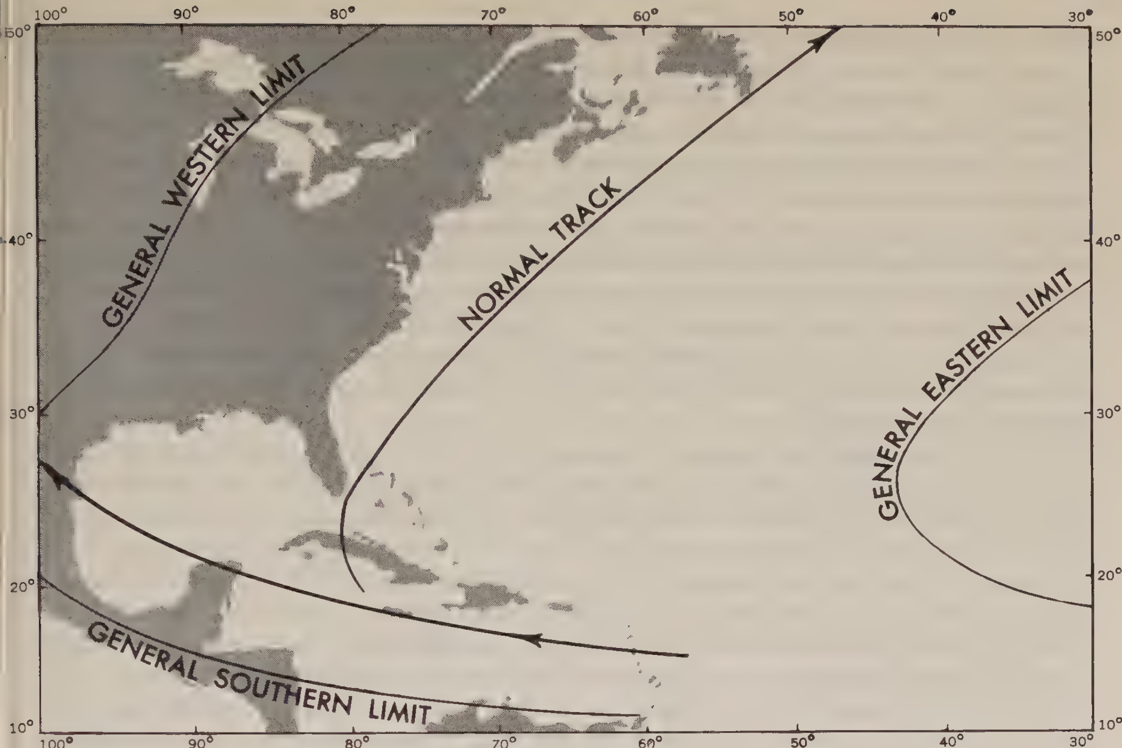

FIGURE 3904c.—Average North Atlantic storm tracks in October.

The differences, both in the averages and in individual tracks, are due to differences in the pressure pattern, particularly the location and movement of highs, which any cyclone tends to avoid.

3905. Life cycle.—The life cycle of a tropical cyclone may be considered to consist of four rather distinct stages, as follows:

Formation. A cyclonic circulation (art. 3813) develops, and wind speed increases to hurricane force (64 knots) over a restricted area near the center. Atmospheric pressure drops to about 1,000 millibars (29.53 inches). This stage may occupy several days, or may be completed in a period of 12 hours or less.

Immaturity. The pressure at the center continues to fall (the storm "deepens") and the wind speed increases, but the storm is still confined to a small area.

Maturity. The pressure at the center remains about the same, but the area of hurricane winds expands, to a radius of perhaps 150 to 200 miles, with winds of gale force (app. R) extending to perhaps 300 miles. Individual storms may differ considerably from these averages.

Decay. The area continues to increase, the pressure at the center rises, and the wind speed decreases. The storm loses its tropical characteristics and gradually dissipates, a process that may require several days over an ocean area. Over land the decay is more rapid.

3906. Origin and development.—Tropical cyclones originate between the doldrums (art. 3805) and the zones of the strongest trade winds. This accounts, at least partly, for the absence of such storms in the South Atlantic, for the Atlantic doldrums remain several degrees north of the equator except for occasional brief periods.

Some of the details regarding the formation of tropical cyclones are not understood, but the fact that such storms form only over water, and dissipate rapidly if they en-

counter land, probably indicates the need for a supply of water vapor. Over the tropical ocean this is abundantly available in the lower portion of the atmosphere. When a low develops over tropical oceans, hot, vapor-laden air flows in from adjacent regions. This air ascends near the center of the low, and condensation occurs. Each pound of water vapor that condenses into cloud or rain liberates approximately 970 British thermal units (art. 3711) of heat. This heat warms the surrounding air, thus increasing further the instability, and hastening the ascent of the air. Thus, the pressure continues to drop and the winds increase in speed, bringing in an increasing quantity of warm, moist air from the regions surrounding the low. At some height, the ascending air flows outward from the center of the cyclonic circulation. This process of inward flow, rising air current, condensation, warming, and high-level outflow causes the low to deepen and the wind speed to increase. Thus, as long as conditions remain suitable, the storm grows more intense.

While the actual mechanics of tropical cyclone formation are somewhat more involved than just described, the essential steps are given. Several theories exist regarding the details of initial formation of the low pressure area. Dropping pressure at the surface due to disturbances at high levels of the atmosphere; interaction of two air streams to produce a cyclonic eddy, causing convergence of surface air and the resulting ascent; and the joining of minor disturbances in the wind and pressure patterns in the atmosphere are all considered possibilities. The process is probably begun by several factors which combine in just the right relationship.

When it becomes fully developed, a tropical cyclone covers a well-defined area, more or less circular in shape, within which the atmospheric pressure decreases rapidly toward the center. This decrease of pressure may amount to a maximum of 0.01 or even 0.02 inch per mile. Because of the rapid decrease of pressure with distance, the wind speed is high, being greatest at the regions of steepest pressure gradient.

At the center of the storm, there is normally an area five to 30 miles in diameter (most often ten to 15 miles) within which the wind speed drops to a relative calm, usually ten to 15 knots or less. This is the **eye of the storm.** Ascending air causes the dense cover of clouds to give way to a thin layer of low clouds with holes through which the sun may shine. Around the edge of the eye, the wind speed increases from the relative calm to the full fury of maximum speed within a distance of a few feet. Here the heavy cloud seems thickest, and the torrential rains surrounding the central area appear concentrated. This is the **wall of the eye.** When a tropical cyclone moves to higher latitude, its eye becomes less clearly defined as the maximum wind moves outward from the center, the wall of the eye becomes more indistinct, and its cloud cover increases.

3907. Locating and tracking a tropical cyclone.—By means of radio, organized meteorological services collect weather observations daily from island stations, ships at sea, and aircraft. When a tropical cyclone is located, usually in its early formative stage, it is followed closely. In the North Atlantic, aircraft of the U. S. Navy and U. S. Air Force, in cooperation with the Weather Bureau, make frequent flights to the vicinity of such storms to provide information needed for tracking the hurricane and determining its intensity. Bulletins are broadcast to ships several times daily, giving information on each storm's location, intensity, and movement. As a further aid, the mariner may obtain weather reports by radio directly from other ships in the vicinity of a tropical cyclone. Radar may be used to follow the movements of the precipitation areas when they are within range.

Although these aids normally prove adequate for locating and avoiding a tropical cyclone, knowledge of the appearance of the sea and sky in the vicinity of such a storm is useful to the mariner. This information is given in article 3908.

3908. The passage of a tropical cyclone at sea is an experience not soon to be forgotten.

An early indication of the approach of such a storm is the presence of a long swell. In the absence of a tropical cyclone, the crests of swell in the deep waters of the Atlantic pass at the rate of perhaps eight per minute. Swell generated by a hurricane is about twice as long, the crests passing at the rate of perhaps four per minute. Swell may be observed several days before arrival of the storm.

When the storm center is 500 to 1,000 miles away, the barometer usually rises a little, and the skies are relatively clear. Cumulus clouds, if present at all, are few in number and their vertical development appears suppressed. The barometer usually appears restless, **pumping** up and down a few hundredths of an inch.

As the tropical cyclone comes nearer, a cloud sequence begins which resembles that associated with the approach of a warm front in middle latitudes (art. 3812). Snow-white, fibrous "mare's tails" (cirrus) appear when the storm is about 300 to 600 miles away. Usually these seem to converge, more or less, in the direction from which the storm is approaching. This convergence is particularly apparent at about the time of sunrise and sunset.

Shortly after the cirrus appears, but sometimes before, the barometer starts a long, slow fall. At first the fall is so gradual that it only appears to alter somewhat the normal daily cycle (two maxima and two minima in the tropics). As the rate of fall increases, the daily pattern is completely lost in the more or less steady fall.

The cirrus becomes more confused and tangled, and then gradually gives way to a continuous veil of cirrostratus. Below this veil, altostratus forms, and then stratocumulus (art. 3714). These clouds gradually become more dense, and as they do so, the weather becomes unsettled. A fine, mist-like rain begins to fall, interrupted from time to time by showers. The barometer has fallen perhaps a tenth of an inch.

As the fall becomes more rapid, the wind increases in gustiness, and its speed becomes greater, reaching a value of perhaps 22 to 40 knots (Beaufort 6–8). On the horizon appears a dark wall of heavy cumulonimbus (art. 3714), the **bar** of the storm. Portions of this heavy cloud become detached from time to time and drift across the sky, accompanied by rain squalls and wind of increasing speed. Between squalls, the cirrostratus can be seen through breaks in the stratocumulus.

As the bar approaches, the barometer falls more rapidly and wind speed increases. The seas, which have been gradually mounting, become tempestuous. Squall lines, one after the other, sweep past in ever increasing number and intensity.

With the arrival of the bar, the day becomes very dark, squalls become virtually continuous, and the barometer falls precipitously, with a rapid increase in wind speed. The center may still be 100 to 200 miles away in a fully developed tropical cyclone. As the center of the storm comes closer, the ever-stronger wind shrieks through the rigging and about the superstructure of the vessel. As the center approaches, rain falls in torrents. The wind fury increases. The seas become mountainous. The tops of huge waves are blown off to mingle with the rain and fill the air with water. Objects at a short distance are not visible. Even the largest and most seaworthy vessels become virtually unmanageable, and may sustain heavy damage. Less sturdy vessels do not survive. Navigation virtually stops as safety of the vessel becomes the prime consideration. The awesome fury of this condition can only be experienced. Words are inadequate to describe it.

If the eye of the storm passes over the vessel, the winds suddenly drop to a breeze as the wall of the eye passes. The rain stops, and the skies clear sufficiently to permit the sun to shine through holes in the comparatively thin cloud cover. Visibility improves. Mountainous seas approach from all sides, apparently in complete confu-

sion. The barometer reaches its lowest point, which may be an inch and a half or two inches below normal in fully developed tropical cyclones. As the wall on the opposite side of the eye arrives, the full fury of the wind strikes as suddenly as it ceased, but from the opposite direction. The sequence of conditions that occurred during approach of the storm is reversed, and pass more quickly, as the various parts of the storm are not as wide in the rear of a storm as on its forward side.

Typical cloud formations associated with a hurricane are shown in figure 3908.

FIGURE 3908.—Typical hurricane cloud formations.

3909. Locating the center of a tropical cyclone.—If intelligent action is to be taken to avoid the full fury of a tropical cyclone, early determination of its location and direction of travel relative to the vessel is essential. The bulletins and forecasts are an excellent general guide, but they are not infallible and may be sufficiently in error to induce a mariner in a critical position to alter course so as to unwittingly increase the danger to his vessel. Often it is possible, using only those observations made aboard ship, to obtain a sufficiently close approximation to enable the vessel to maneuver to the best advantage.

As stated in article 3908, the presence of an exceptionally long swell is usually the first visible indication of the existence of a tropical cyclone. In deep water it approaches from the general direction of origin (the position of the storm center *when the swell was generated*). However, in shoaling water this is a less reliable indication because the direction is changed by refraction, the crests being more nearly parallel to the bottom contours (art. 3307).

When the cirrus clouds appear, their point of convergence provides an indication of the direction of the storm center. If the storm is to pass well to one side of the observer, the point of convergence shifts slowly in the direction of storm movement. If the storm center will pass near the observer, this point remains steady. When the bar (art. 3908) becomes visible, it appears to rest upon the horizon for several hours. The darkest part of this cloud is in the direction of the storm center. If the storm is to pass to one side, the bar appears to drift slowly along the horizon. If the storm is heading directly toward the observer, the position of the bar remains fixed. Once within the area of the dense, low clouds, one should observe their direction of move-

ment, which is almost exactly along the isobars, with the center of the storm being 90° from the direction of cloud movement (left of direction of movement in the northern hemisphere, and right in the southern hemisphere).

The winds are probably the best guide to the direction of the center of a tropical cyclone. The circulation is cyclonic (art. 3813), but because of the steep pressure gradient near the center, the winds there blow with greater violence and are more nearly circular than in extratropical cyclones.

According to Buys Ballot's law (art. 3813) an observer who faces into the wind has the center of the low pressure on his right in the northern hemisphere, and on his left in the southern hemisphere, and in each case somewhat behind him. If the wind followed circular isobars exactly, the center would be exactly eight points, or 90°, from dead ahead when facing into the wind. However, the track of the wind is usually inclined somewhat toward the center, so that the angle from dead ahead varies between perhaps 8 and 12 points (90° to 135°). The inclination varies in different parts of the same storm. It is least in front of the storm, and greatest in the rear, since the actual wind is the vector sum of that due to the pressure gradient and the motion of

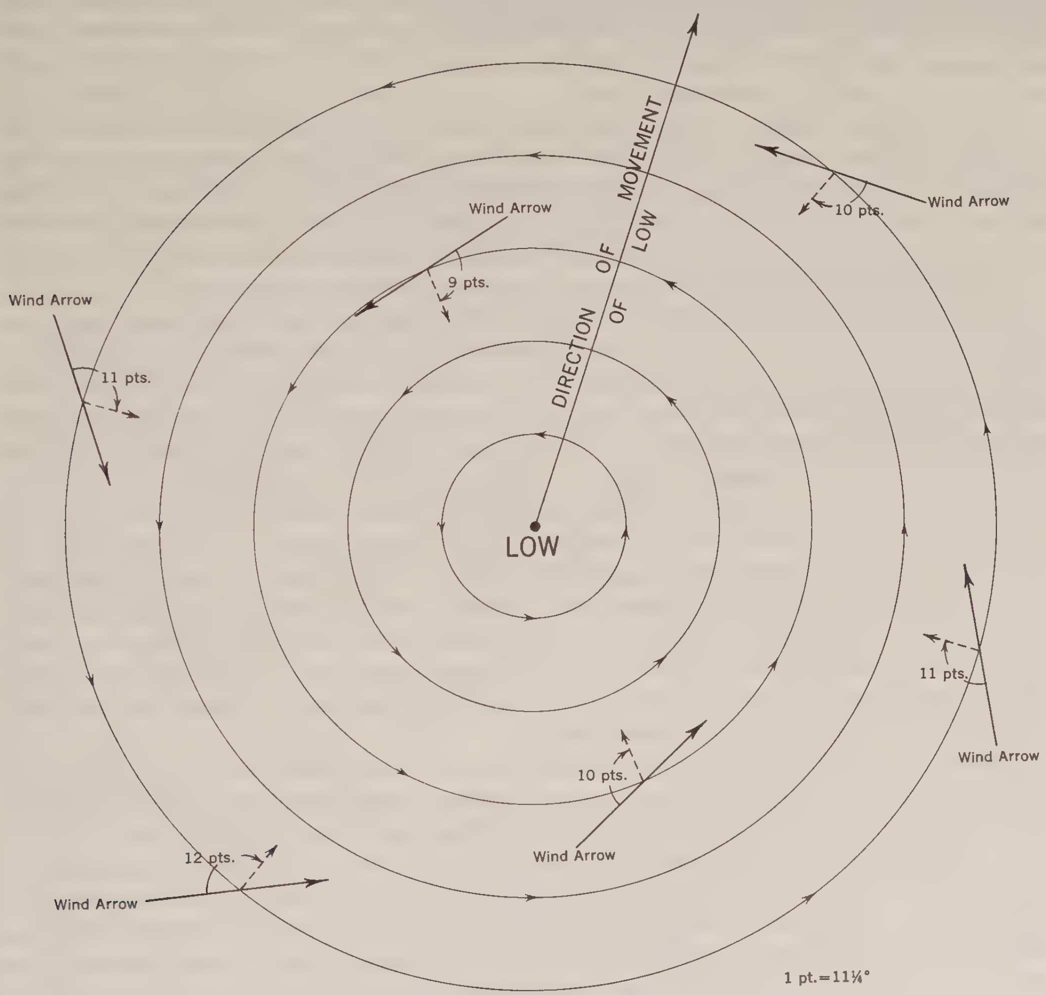

FIGURE 3909a.—Approximate relationship of wind to isobars and storm center in the northern hemisphere.

the storm along the track. A good average is perhaps ten points in front, and 11 or 12 points in the rear. These values apply when the storm center is still several hundred miles away. Closer to the center, the wind blows more nearly along the isobars, the inclination being reduced by one or two points at the wall of the eye. Since wind direction usually shifts temporarily during a squall, its direction at this time should not be used for determining the position of the center. The approximate relationship of wind to isobars and storm center in the northern hemisphere is shown in figure 3909a.

When the center is within radar range, it might be located by this equipment. However, since the radar return is predominantly from the rain, results can be deceptive, and other indications should not be neglected. Figure 3909b shows a typical radar PPI presentation of a tropical cyclone.

Distance from the storm center is more difficult to determine than direction. Radar is perhaps the best guide. However, the rate of fall of the barometer is some indication. If a vessel is hove-to in front of a storm which is advancing directly toward it, the fall of pressure per hour might be about as shown in figure 3909c. However, this is an imperfect indication, for the rate of fall may be quite erratic, and will vary somewhat with the depth of the low at the center, the speed of the storm center along its track, and the stage in the life cycle of the storm. The usefulness of this information is further reduced by the fact that a vessel would not normally remain hove-to in the path of a tropical cyclone.

3910. Maneuvering to avoid the storm center.—The safest procedure with respect to tropical cyclones is to avoid them. If action is taken sufficiently early, this is simply a matter of setting a course that will take the vessel well to one side of the probable track of the storm, and then continuing to plot the positions of the storm center, as given in the weather bulletins, revising the course as needed.

However, such action is not always possible. If one finds himself within the storm area, the proper action to take depends in part upon his position relative to the storm center and its direction of travel. It is customary to divide the circular area of the storm into two parts. In the northern hemisphere, that part to the *right* of the storm track (facing in the direction *toward* which the storm is moving) is called the **dangerous semicircle.** It is considered dangerous because (1) the actual wind *speed* is greater than that due to the pressure gradient alone, since it is augmented by the forward motion of the storm, and (2) the *direction* of the wind and sea is such as to carry a vessel into the path of the storm (in the forward part of the semicircle). The part to the left of the storm track is called the **navigable semicircle.** In this part, the wind is decreased by the forward motion of the storm, and the wind blows vessels away from the storm track (in the forward part). Because of the greater wind speed in the dangerous semicircle, the seas are higher here than in the navigable semicircle. In the southern hemisphere, the dangerous semicircle is to the left of the storm track, and the navigable semicircle is to the right of the storm track.

A plot of successive positions of the storm center should indicate the semicircle in which a vessel is located. However, if this is based upon weather bulletins, it is not a reliable guide because of the lag between the observations upon which the bulletin is based and the time of reception of the bulletin, with the ever present possibility of a change in the direction of motion of the storm. The use of one's radar eliminates this lag, but the return is not always a true indication of the center. Perhaps the most reliable guide is the wind. Within the cyclonic circulation, a *veering* wind (one changing direction to the right in the northern hemisphere and to the left in the southern hemisphere) indicates a position in the dangerous semicircle, and a *backing* wind (one changing in a direction opposite to a veering wind) indicates a position in the navigable semicircle. However, if a vessel is underway, its motion should be considered. If it is

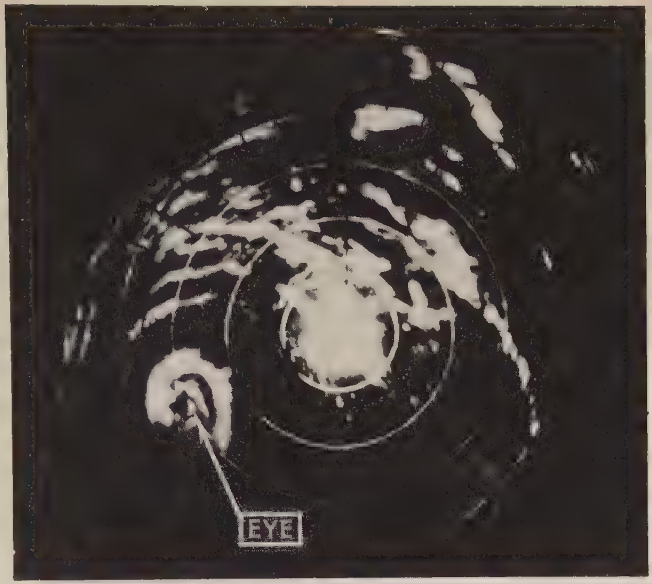

FIGURE 3909b.—Typical radar PPI presentation of a tropical cyclone.

outrunning the storm or pulling rapidly toward one side (which is not difficult during the early stages of a storm, when its speed is low), the opposite effect occurs. This should usually be accompanied by a rise in atmospheric pressure, but if motion of the vessel is nearly along an isobar, this may not be a reliable indication. If in doubt, the safest action is usually to stop long enough to determine definitely the semicircle. The loss in valuable time may be more than offset by the minimizing of the possibility of taking the wrong action and increasing the danger to the vessel. If the wind direction remains steady (for a vessel which is stopped), with increasing speed and falling barometer, the vessel is in or near the path of the storm. If it remains steady with decreasing speed and rising barometer, the vessel is on the storm track, behind the center.

The first action to take if one finds himself within the cyclonic circulation, is to determine the position of his vessel with respect to the storm center. While the vessel can still make considerable way through the water, a course should be selected to take it as far as possible from the center. If the vessel can move faster than the storm, it is a relatively simple matter to outrun the storm if sea room permits. But when the storm is faster, the solution is not as simple. In this case, the vessel, if ahead of the storm, will approach nearer to the center. The problem is to select a course that will produce the greatest possible minimum distance. This is best determined by means of a relative movement plot, as shown in the following example solved on a maneuvering board (art. 1212):

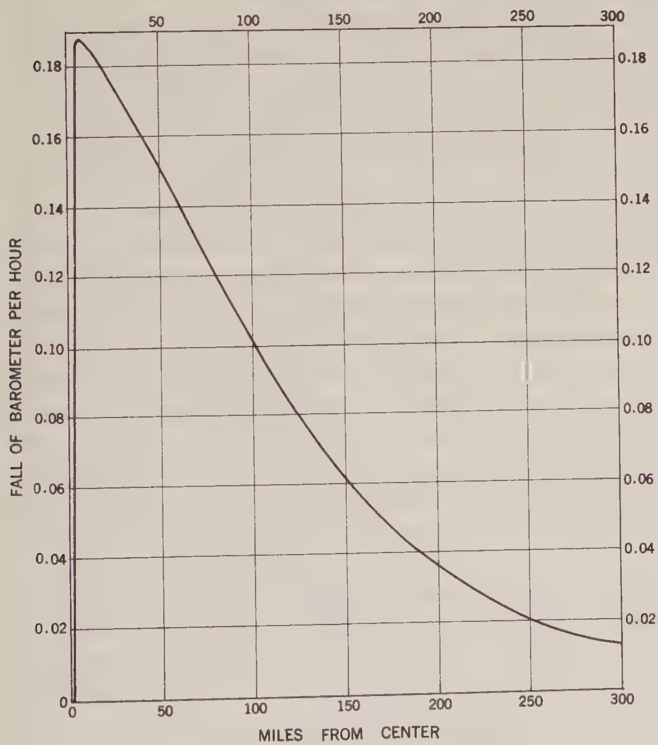

FIGURE 3909c.—Typical average pressure drop as tropical cyclone approaches.

Example.—A tropical cyclone is estimated to be moving

in direction 320° at 19 knots. Its center bears 170°, at an estimated distance of 200 miles from a vessel which has a maximum speed of 12 knots.

Required.—(1) The course to steer at 12 knots to produce the greatest possible minimum distance between the vessel and the storm center.

(2) The distance of the storm center at nearest approach.

(3) Elapsed time until nearest approach.

Solution (fig. 3910).—Consider the vessel remaining at the center of the plot throughout the solution, as on a radar PPI.

(1) Plot point *C* at a distance of 200 miles (scale 20:1) in direction 170° from the center of the diagram, to locate the position of the storm center relative to the vessel. From the center of the diagram, draw *RA*, the speed vector of the storm center, in direction 320°, speed 19 knots (scale 2:1). From *A* draw a line tangent to the 12-knot speed circle (labeled 6 at scale 2:1) *on the side opposite the storm center.* From the

FIGURE 3910.—Solution to determine course for avoiding storm center.

center of the diagram draw a perpendicular to this tangent line, locating point B. The line RB is the required speed vector for the vessel. Its direction, 011°, is the required course.

(2) The path of the storm center *relative to the vessel*, will be along a line from C in the direction BA, if both storm and vessel maintain course and speed. The point of nearest approach will be at D, the foot of a perpendicular from the center of the diagram. This distance, at scale 20:1, is 187 miles.

(3) The length of the vector BA (14.8 knots) is the speed of the storm with respect to the vessel. Mark this on the lowest scale of the nomogram at the bottom of the diagram. The relative distance CD is 72 miles, by measurement. Mark this (scale 10:1) on the middle scale at the bottom of the diagram. Draw a line between the two points and extend it to intersect the top scale at 29.2 (292 at 10:1 scale). The elapsed time is therefore 292 minutes, or 4 hours 52 minutes, or 5 hours approximately.

Answers.—(1) C 011°, (2) D 187 mi., (3) t 5^h (approximately).

The storm center will be dead astern at its nearest approach.

As a very general rule, for a vessel in the northern hemisphere, safety lies in placing the wind on the starboard bow in the dangerous semicircle and on the starboard quarter in the navigable semicircle. If on the storm track ahead of the storm, the wind should be put about two points on the starboard quarter until the vessel is well within the navigable semicircle, and the rule for that semicircle then followed. A study of figure 3909a should indicate why these headings are desirable. In the southern hemisphere the same rules hold, but with respect to the port side. With a faster than average vessel, the wind can be brought a little farther aft in each case. However, as the speed of the storm increases along its track, the wind should be brought farther forward. If land interferes with what would otherwise be the best maneuver, the solution should be altered to fit the circumstances. If the speed of a vessel is greater than that of the storm, it is possible for the vessel, if behind the storm, to overtake it. In this case, the only action usually needed is to slow enough to let the storm pull ahead.

In all cases, one should be alert to changes in the direction of movement of the storm center, particularly in the area where the track normally curves toward the pole. If the storm maintains its direction and speed, the ship's course should be maintained as the wind shifts.

If it becomes necessary for a vessel to heave to, the characteristics of the vessel should be considered. A power vessel is concerned primarily with damage by direct action of the sea. A good general rule is to heave to with head to the sea in the dangerous semicircle or stern to the sea in the navigable semicircle. This will result in greatest amount of headway away from the storm center, and least amount of leeway toward it. If a vessel handles better with the sea astern or on the quarter, it may be placed in this position in the navigable semicircle or in the rear half of the dangerous semicircle, but *never* in the forward half of the dangerous semicircle. It has been reported that when the wind reaches hurricane speed and the seas become confused, some ships ride out the storm best if the engines are stopped, and the vessel is permitted to seek its own position. In this way, it is said, the ship rides *with* the storm instead of fighting *against* it.

In a sailing vessel, while attempting to avoid a storm center, one should steer courses as near as possible to those prescribed above for power vessels. However, if it becomes necessary for such a vessel to heave to, the wind is of greater concern than the sea. A good general rule always is to heave to on whichever tack permits the shifting wind to draw aft. In the northern hemisphere this is the starboard tack in

the dangerous semicircle and the port tack in the navigable semicircle. In the southern hemisphere these are reversed.

While each storm requires its own analysis, and frequent or continual resurvey of the situation, the general rules for a steamer may be summarized as follows:

NORTHERN HEMISPHERE

Right or dangerous semicircle.—Bring the wind on the starboard bow (045° relative), hold course and make as much way as possible. If obliged to heave to, do so with head to the sea.

Left or navigable semicircle.—Bring the wind on the starboard quarter (135° relative), hold course and make as much way as possible. If obliged to heave to, do so with stern to the sea.

On storm track, ahead of center.—Bring the wind two points on the starboard quarter (157°5 relative), hold course and make as much way as possible. When well within the navigable semicircle, maneuver as indicated above.

On storm track, behind center.—Avoid the center by the best practicable course, keeping in mind the tendency of tropical cyclones to curve northward and eastward.

SOUTHERN HEMISPHERE

Left or dangerous semicircle.—Bring the wind on the port bow (315° relative), hold course and make as much way as possible. If obliged to heave to, do so with head to the sea.

Right or navigable semicircle.—Bring the wind on the port quarter (225° relative), hold course and make as much way as possible. If obliged to heave to, do so with stern to the sea.

On storm track, ahead of center.—Bring the wind two points on the port quarter (202°5 relative), hold course and make as much way as possible. When well within the navigable semicircle, maneuver as indicated above.

On storm track, behind center.—Avoid the center by the best practicable course, keeping in mind the tendency of tropical cyclones to curve southward and eastward.

Whenever a tropical cyclone is encountered, the wise procedure is to begin preparing the vessel for heavy weather in sufficient time to permit thorough preparation, so that damage may be minimized. One should be particularly careful to keep free surfaces of liquids to a minimum.

3911. Coastal effects.—The high winds of a tropical cyclone inflict widespread damage when such a storm leaves the ocean and crosses land. Aids to navigation may be blown out of position or destroyed. Craft in harbors, unless they are properly secured, drag anchor or are blown against obstructions. Ashore, trees are blown over, houses are damaged, power lines are blown down, etc. The greatest damage usually occurs in the dangerous semicircle a short distance from the center, where the strongest winds occur. As the storm continues on across land, its fury subsides faster than it would if it had remained over water.

Along the coast, particularly, greater damage may be inflicted by water than by the wind. There are at least four sources of water damage. First, the unusually high seas generated by the storm winds pound against shore installations and craft in their way. Second, the continued blowing of the wind toward land causes the water level to increase perhaps three to ten feet above its normal level. This **storm tide,** which may begin when the storm center is 500 miles or even farther from the shore, gradually increases until the storm passes. The highest storm tides are caused by a slow-moving tropical cyclone of large diameter, because both of these effects result in greater duration of wind in the same direction. The effect is greatest in a partly enclosed body

of water, such as the Gulf of Mexico, where the concave coastline does not readily permit the escape of water. It is least on small islands, which present little obstruction to the flow of water. Third, the furious winds which blow around the wall of the eye create a ridge of water called a **storm wave,** which strikes the coast and often inflicts heavy damage. The effect is similar to that of a **seismic sea wave,** caused by an earthquake in the ocean floor. Both of these waves are popularly called **tidal waves.** Storm waves of 20 feet or more have occurred. About three or four feet of this is due to the decrease of atmospheric pressure, and the rest to winds. Like the damage caused by wind, that due to high seas, the storm tide, and the storm wave is greatest in the dangerous semicircle, near the center. The fourth source of water damage is the heavy rain that accompanies a tropical cyclone. This causes floods that add to the damage caused in other ways.

When proceeding along a shore recently visited by a tropical cyclone, a navigator should remember that time is required to restore aids to navigation which have been blown out of position or destroyed. In some instances the aid may remain but its light, sound apparatus, or radiobeacon may be inoperative. Landmarks may have been damaged or destroyed.

PART EIGHT

HYDROGRAPHY

PART EIGHT

HYDROGRAPHY

CHAPTER XL

INSTRUMENTS FOR HYDROGRAPHIC SURVEYING

4001. Introduction.—Although the expression "hydrographic surveying" denotes investigation of water areas to obtain information for use in making nautical charts, land surveying methods are frequently used to establish points on shore from which positions of all hydrographic observations such as soundings, currents, etc., can be related. Therefore, this chapter describes such instruments as the astrolabe, theodolite, level, and special drafting equipment, as well as tide gages, current meters, and other instruments directly associated with hydrography. Instruments used in hydrographic surveying, but described elsewhere, include the sextant (ch. XV), echo sounder (art. 619), and electronic equipment (ch. XIII). In general, surveying instruments are characterized by a high order of accuracy, as compared with navigation instruments.

4002. Astrolabe.—Unlike the earlier instrument of the same name (art. 124), the modern **astrolabe** is used in hydrographic surveying to determine the instant at which various celestial bodies arrive at a preselected altitude. From a number of such

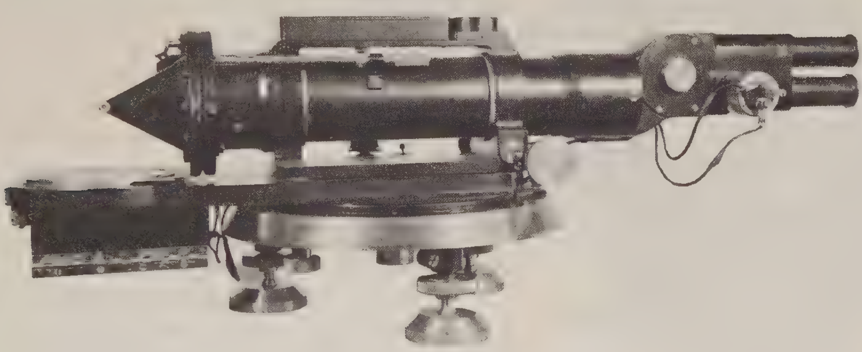

FIGURE 4002a.—A prismatic astrolabe.

observations, the position of the instrument can be calculated. Astrolabes now available use an altitude of 45° or 60°.

As its name implies, the **prismatic astrolabe** (fig. 4002a) depends upon an accurately-ground prism to maintain the fixed angle of observation. In addition, the prism permits the observation of a second image of a star by reflection from an artificial horizon, which is a small pan of mercury placed below the prism. In figure 4002b, a light ray (R) from a star enters directly the upper surface of the prism and is reflected through the horizontal observing telescope. A parallel ray (R′) from the same star is reflected from the mercury surface, enters the lower surface of the prism, and is then reflected through the telescope. Since the latter image is a doubly reflected one, its apparent motion will be opposite that of the former (fig. 4002b, rays (a) and (a′) and inset (1)). When the direct and reflected light rays are perpendicular to the upper and lower surfaces of the prism, respectively, the two images are coincident and the star is at the altitude fixed by the angle between the surfaces of the prism.

In practice, the prism is turned slightly on an axis coincident with the telescope axis so that the images will, at the fixed altitude, be side by side on a horizontal line

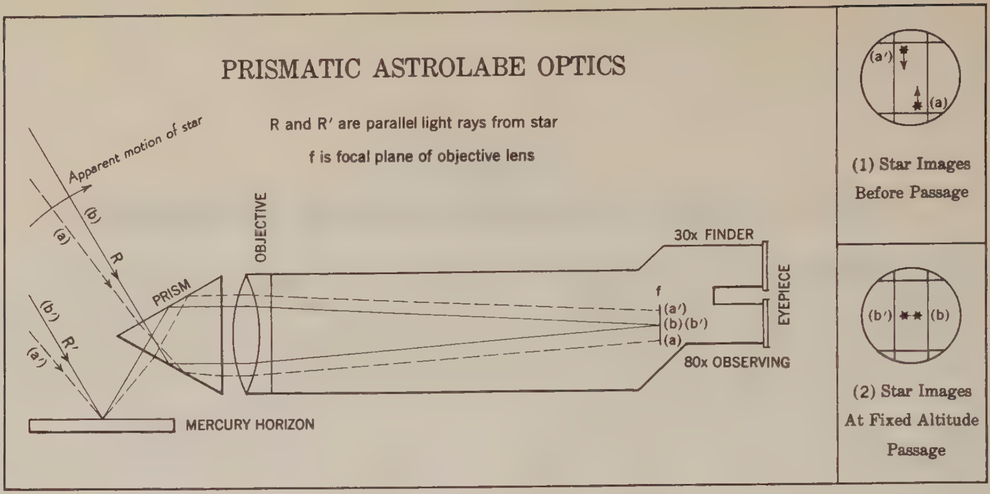

FIGURE 4002b.—Optics of the prismatic astrolabe.

(fig. 4002b, rays (b) and (b′) and insert (2)) rather than coincident. This permits easier, more accurate observation.

In addition to the basic parts already mentioned, the prismatic astrolabe is provided with level bubbles and three leveling screws to adjust it to the horizontal. For orienting to north and setting at desired azimuths, it is equipped with a magnetic compass and an azimuth circle. Adjusting screws are provided for collimation; that is, making the vertical surface of the prism perpendicular to the axis of the telescope. There is also an erecting screw which rotates the prism about the axis of the telescope. Flashlight batteries supply power to illuminate the azimuth circle and reticle, the intensity of the latter being controlled by a rheostat.

A prism actuated by a lever deflects the light rays upward to a 30-power, wide field-of-view eyepiece to facilitate finding the star. Once the star is located, final observations are made through the 80-power observing eyepiece. Accessories for screening the mercury from wind and dust, and equipment for cleaning the surface of the mercury are included with the instrument.

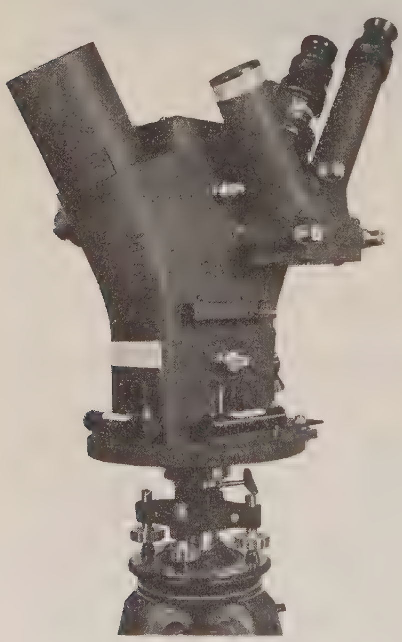

FIGURE 4002c.—A pendulum astrolabe.

The **pendulum astrolabe** (fig. 4002c) fixes the observation altitude by directing the light rays from a star down a 60° objective tube to a pendulum-supported horizontal mirror, from which it is reflected up a 60° eyepiece tube. Thus, in a sense, it is a telescope bent at 60° with a pendulum mirror to reflect the light rays accordingly (fig. 4002d). Since only one star image is seen, the exact time of star passage is noted as being the mean of the times at which it passes a set of horizontal cross hairs.

In addition to the 80-power observing telescope, it has an 11-power finder telescope. This instrument also has internal illumination and is provided with means for leveling and setting in azimuth.

4003. Timing equipment.—The timing equipment used in conjunction with astrolabes consists of a **chronometer,** a **radio,** a **chronograph,** and a break-circuit **key** (fig. 4003). The chronometer is set to run on sidereal time and is connected through an amplifier to the chronograph, which records a tick mark on moving paper at each one-second break except the 59th second of every minute. This is omitted so that the beginning of each minute can be easily identified on the record.

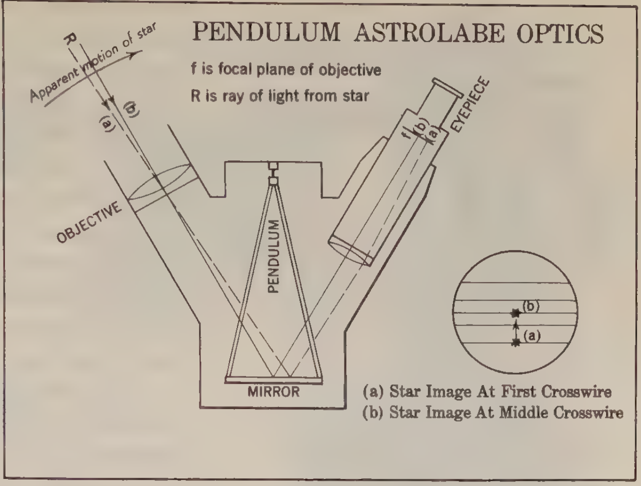

Figure 4002d.—Optics of the pendulum astrolabe.

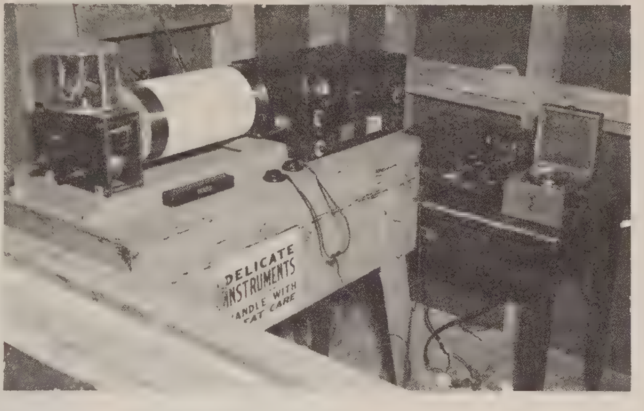

Figure 4003.—Timing equipment.

The radio, also, is connected to the chronograph recorder through the amplifier, and is used to receive standard time signals for determining chronometer correction and rate. The break-circuit key is tapped by the observer at the instant of star passage, making a tick mark on the chronograph paper. The chronometer time of star passage can be scaled off the chronograph record. By application of chronometer correction and rate, one can determine the GMT of the observation.

4004. Theodolite.—A **theodolite** is an instrument designed to measure precise horizontal and vertical angles. Thus, it can be used for determining the bearing (called "azimuth" by surveyors) of a line by observing the angle between that line and the azimuth line of a star. It can be used to measure the angles in a triangulation net, and to measure vertical angles for the trigonometric computation of elevations.

The **direction theodolite** (fig. 4004a) consists essentially of two graduated circles (one horizontal and one vertical), equipment for leveling and centering the instrument, an observing telescope, and an eyepiece for reading the circles. Horizontal angles can be read directly to the nearest 0.2 second of arc on the instrument illustrated. A smaller, lighter model can be read directly to the nearest second of arc, and tenths can be estimated.

Both circles are completely enclosed, and are read at one eyepiece through a system of prisms within the instrument. As the upper portion of the instrument turns about a vertical axis, two sets of prisms scan diametrically opposite sides of the horizontal circle. This upper portion can be clamped and final pointing on target can be made with a slow-motion tangent screw. The vertical cross hair is brought exactly on target, and the instrument is collimated and read. The horizontal circle can be set at any desired initial reading.

When the telescope is turned about its horizontal axis, two sets of prisms scan

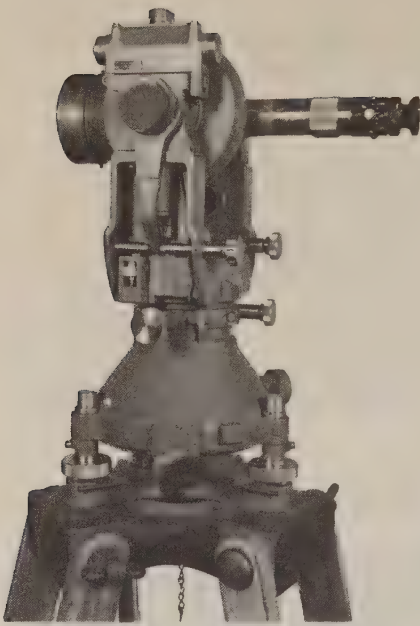

FIGURE 4004a.—A direction theodolite.

diametrically opposite sides of the vertical circle. This motion also has a clamp and slow-motion tangent screw. Collimation is effected before reading. The vertical circle is read through the same eyepiece as the horizontal circle, by turning a knob near the bottom of the rear face of the right-hand standard. When the line on this knob is horizontal, the horizontal circle is seen, and when the line is vertical, the vertical circle is seen. Since the vertical circle reads zero when the telescope is pointed directly toward the zenith, the angles read are zenith distances.

Accessory equipment for this type instrument includes an optical centering device, internal illumination for night observations, prismatic eyepieces, and accurate levels. Complete instructions for use of the instrument are furnished by the manufacturer.

The **repeating theodolite** (fig. 4004b), unlike the direction theodolite, has a lower motion clamp screw and slow-motion tangent screw. Thus, with the upper portion clamped and the lower motion free, the horizontal circle and upper portion of the instrument carrying the telescope and two verniers rotate as a unit about the vertical axis. With the lower motion clamped and the upper motion free, the circle remains fixed and the upper portion only rotates, indicating angles by the position of the verniers relative to the horizontal circle. Also, the circle is exposed at the verniers for reading through a magnifying glass. These verniers can be read to the nearest ten seconds of arc.

Since the vertical circle is graduated to read zero when the telescope is horizontal, other readings are either elevation or depression angles. The verniers of the vertical circle read directly to the nearest 15 seconds of arc.

4005. Transit.—The **surveyor's transit** (fig. 4005a) is similar to the repeating theodolite, except that it is smaller, lighter, and less precise. It rests on four leveling screws rather than three, and some models read only to the nearest minute of arc.

The **camera transit** (fig. 4005b) consists essentially of a surveyor's transit with a camera mounted between widely separated standards. A transit telescope is mounted on top of the camera. In use, the instrument is pointed on a known con-

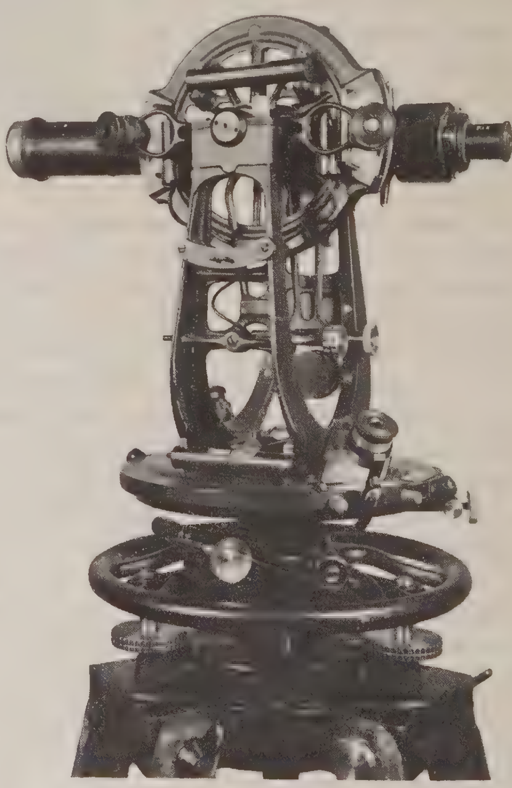

FIGURE 4004b.—A repeating theodolite.

FIGURE 4005a.—A surveyor's transit.

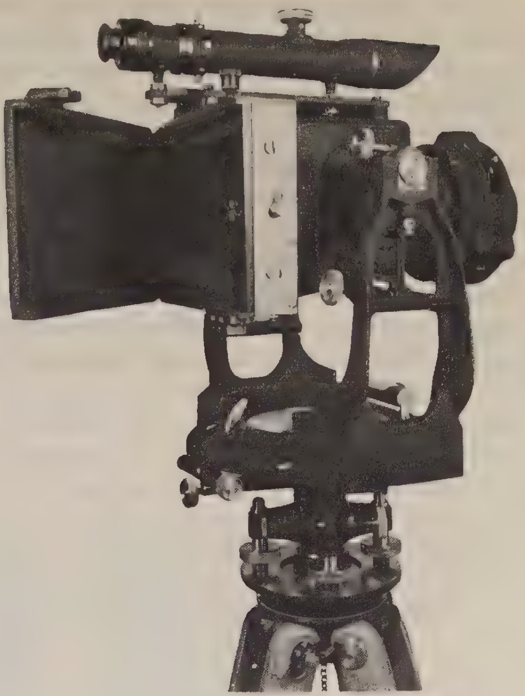

FIGURE 4005b.—A camera transit.

trol point as if it were an ordinary transit. A photograph is taken, then the instrument is turned in azimuth and another picture is obtained. This is repeated until a complete panorama of overlapping pictures is obtained around the observation point. During this procedure, the instrument may be pointed on other known points to obtain additional control. Prints of these pictures can be used for determining angles to additional points for supplementary horizontal and vertical control. A somewhat similar instrument, consisting of a combination camera and theodolite, is called a **phototheodolite.**

4006. Level.—The **precise level** (fig. 4006) is used for determining precise elevation differences between two points. The instrument illustrated has generally supplanted the "Wye" level formerly used in most hydrographic surveys. The split image of a sensitive level bubble is seen through an eyepiece adjacent to the telescope eyepiece, and as long as the two parts remain matched, the telescope line of sight is in the horizontal.

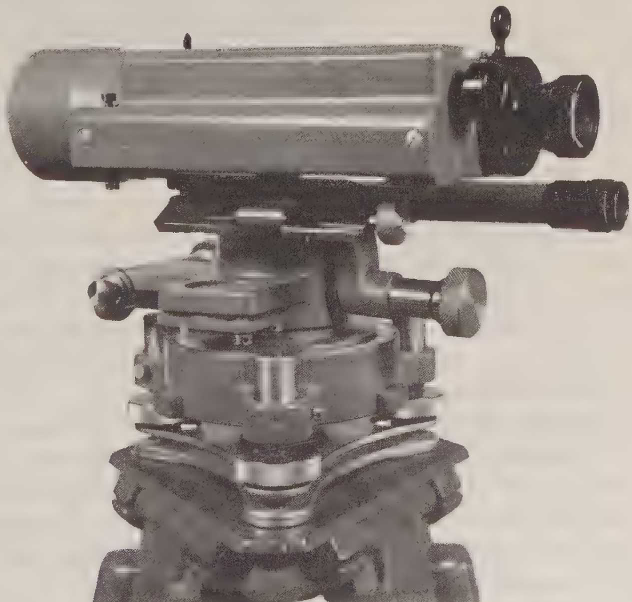

FIGURE 4006.—A precise level.

For reconnaissance or other rough work, a small hand level may be used. The **Locke type hand level** determines only a horizontal line of sight. The **Abney type** adds a small vertical arc which can be used for observing elevation angles. Neither should be considered a precision instrument.

4007. Distance measurement can be accomplished by any of several different methods and procedures. For precise work, special **tapes** which have a low coefficient of expansion and have been calibrated by the National Bureau of Standards under controlled temperature, tension, and support conditions are used. They are used in the field under standard tension and support, and the temperatures and support elevations are observed and recorded so that corrections can be applied to the measured distances to adjust them to the corrected horizontal distances. If such precision is not required, a surveyor's steel tape may be used.

Slightly less precise, but more rapid, is the measurement of distance by means of a **subtense bar** (fig. 4007). In this method, a direction theodolite is used to measure the angle between the end points of a distant Invar bar. The bar is mounted horizontally on a tripod and is oriented to be perpendicular to the line between its center and the theodolite by a small telescope mounted on it for this purpose. The size of the angle subtended by this bar is a measure of the distance from theodolite to bar. Tables

FIGURE 4007.—A subtense bar.

of angles and corresponding distances are available from the manufacturer, or can be computed.

Another still less precise method of measuring distance is by a **stadia,** a graduated rod. In addition to the cross hairs used in angle measurement, a transit is equipped with two other horizontal cross hairs so spaced that they will subtend one foot on a vertical stadia rod at 100 feet distance. At any distance the stadia cross hairs will intercept on the rod a length of about $\frac{1}{100}$th of that distance. If the ratio is other than 1:100, a stadia constant is furnished with the instrument or can be determined by comparing a stadia measurement of distance with the value of that same distance as carefully measured with a tape.

4008. Bottom samplers.—Samples of the bottom are obtained by means of **snapper** or **scoopfish** type **bottom samplers.** The former is secured to the base of a sounding lead and is used while the craft is lying to. Two clamshell-shaped castings are snapped together by a heavy spring when triggered by hitting the bottom, and a handful-size sample is thus obtained. The scoopfish is designed for use with the vessel underway. It is essentially a hollow tube with diving fins aft, and a special towing bridle. When properly set and towed, it dives to the bottom. When it strikes the bottom, a sample is forced into the tube, the bridle suspension point is automatically shifted forward so

that the instrument will no longer dive but can be hoisted up, and a cover flips into position over the forward end of the tube to retain the sample.

4009. Tide gage.—It is necessary to obtain as complete a record as possible of the tide in the survey area during operations. The information furnished by this record is used to determine the reference plane, or datum, for all heights and depths. It is also used for adjusting all original observations to that datum, and from it is computed the tidal data which is printed on the chart, such as mean sea level, spring rise, neap rise, lunitidal interval, etc.

The **portable automatic recording tide gage** (fig. 4009) is a light, compact instrument which records on single sheets of special paper a graph of the tide. The paper is clipped onto a drum which is rotated at one-half revolution per day by an eight-day clock movement contained inside. A float is suspended by a wire inside a pipe-float well

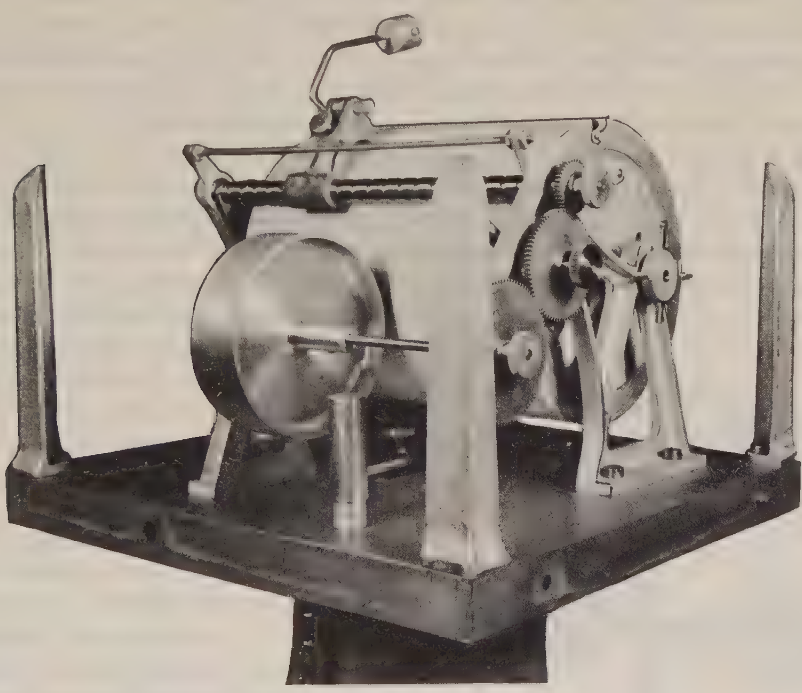

FIGURE 4009.—A portable automatic recording tide gage.

which protects it from wave and current action, yet permits long-period water level variations through a small aperture in the bottom of the pipe.

The float wire is guided up to the gage over an idler pulley centered over the top of the pipe. At the gage, the wire is wound around a grooved drum. Inside this drum is a spring which keeps tension on the wire so that as the float rises with the water, the drum rotates and takes up the slack. When the water level falls, the weight of the float overcomes the tension of the spring and the drum rotates in the opposite direction. The axle of the float-wire drum is geared to a long-pitch screw on which rides a stylus. This screw moves the stylus across the paper parallel to the axis of the record drum. Thus, while the record drum is rotated by its clock, the stylus is moved back and forth across the drum as the water level rises and falls. The record paper is black or red and coated with white wax. The stylus scratches the wax, drawing a graph of the water level variations with time as abscissa around the drum and height as ordinate across the drum.

Record paper is furnished in different height scales and corresponding sets of gears are used to vary the stylus motion. Thus, the instrument can be adapted for use in accordance with the range of the tide.

The **standard automatic recording tide gage** operates in a similar manner, with the following exceptions: the paper, fed from a supply roller, passes over a main roller across which a pencil rides, and is taken up by a receiving roller. The paper is long enough to accommodate a continuous one-month tide record. Two clocks are used; one to advance the paper by rotating the main roller, and the other to strike hour marks on the paper. The receiving roller, which winds the paper, is actuated by a weight suspended by a cord which is wound around a drum. Friction springs retard the supply roll so it will not unwind too fast. A counterpoise weight is suspended by a wire which runs over a drum secured to the same shaft as the float-wire drum. This keeps tension on the float wire and takes up the slack as the tide rises. In addition to the tide-marking pencil, this instrument is equipped with a datum-marking pencil. This is set to draw a straight line at the datum height. Scale changes to accommodate various ranges of tide are accomplished by using float-wire drums of varying circumference, different pencil screw pitch, and corresponding counterpoise weights.

A number of other methods may be used for observing tidal data. Most important is the **tide staff.** This is a graduated board from which the water height is read at regular time intervals. It can be installed vertically or, with properly exaggerated graduations, inclined. The latter installation is best used in calm water with small range of tide. Other devices for measuring tide include the **float gage, tape gage,** and **pipe gage.** These are all nonregistering. A number of gages have been designed to operate on the bottom. Their mechanisms are actuated by pressure changes caused by variations in the depth of water. This type of gage is not in general use.

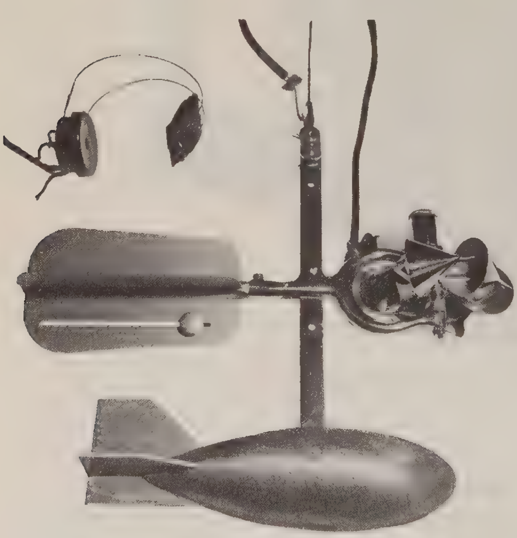

Figure 4010.—A device for measuring current speed.

4010. Current observations are also an integral part of hydrographic surveying. When printed on the chart, the information is valuable to navigators, especially in channels and other areas of limited maneuvering space. Types and designs of **current meters** are so varied that only those features which are common to most of them will be presented here.

In general, current speed is determined by counting the number of revolutions of a propeller per unit time. Propeller turns are counted in many ways. One type is illustrated in figure 4010.

Direction of the current is indicated by one of many methods of determining the heading of the meter relative to a compass magnet. The meters are kept headed into the current by fins.

4011. Drafting instruments.—Certain drafting instruments are of special value in plotting the information obtained in hydrographic surveys. Distance measurements in chart drafting are taken from a metal **diagonal metric scale** direct to the nearest 0.0001 meter. This device consists of a flat metal bar a little more than one meter long. Vertical lines (fig. 4011a) are spaced at intervals of one centimeter (0.01 meter) and graduated 0 to 100. To the left of the meter is an additional centimeter with diagonal

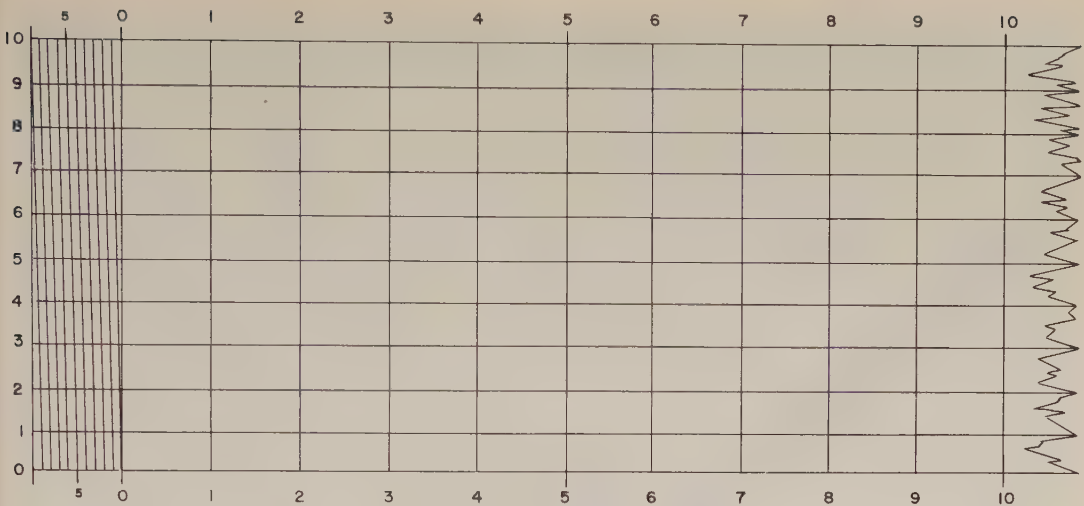

FIGURE 4011a.—A diagonal metric scale.

lines permitting measurement to two additional decimal places. Along the bottom horizontal line this additional centimeter is divided into ten equal parts. Hundredths are obtained by making the measurement on the corresponding horizontal line. Thus, a distance of 7.43 centimeters is measured horizontally along line 3, from vertical line 7 on the right to diagonal line 4 on the left. When the distance is greater than can be accommodated by the usual dividers or compasses, **beam compasses** (fig. 4011b) are used. This consists of a wood or metal bar on which slide two beam heads carrying steel points, exchangeable for an inking pen or pencil point. A thumb screw on each point clamps it in position on the bar, and one is equipped with a slow-motion screw for fine adjustment.

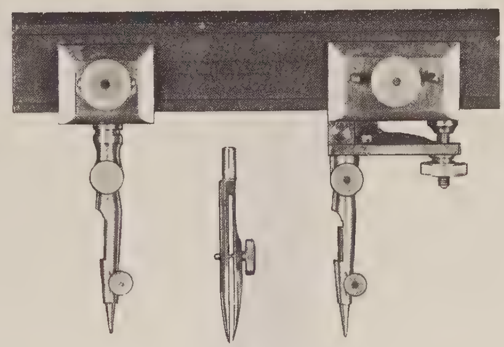

FIGURE 4011b.—Beam compasses.

A **three-arm protractor** is used for rapid plotting of three-point fixes. It can also be used for plotting angles to secondary survey stations. The center arm of a three-arm protractor is secured to, or a part of, a graduated circle. The left and right arms are pivoted about the center of this circle and are equipped with clamping devices. A plastic type has a two-minute vernier on each movable arm, and angles can be set to the nearest estimated one minute. This type is easy and rapid when plotting three-point fixes on signals which are comparatively near the boat position. For more precise plotting and for fixes on distant signals, the metal protractor (fig. 4011c) is used. The verniers of this instrument read to the nearest one minute. A magnifying glass is attached to facilitate reading the verniers, and slow motion screws are provided to permit fine adjustments. Detachable extension arms are furnished for use on distant objects. Since only one arm can be set to small angles down to zero, this instrument is manufactured in left- and right-hand models, on which the left and right angles, respectively, may be set to zero.

Proportional dividers (fig. 4011d) are an aid to transferring measurements between charts or other drawings which are not to the same scale. This device consists of two

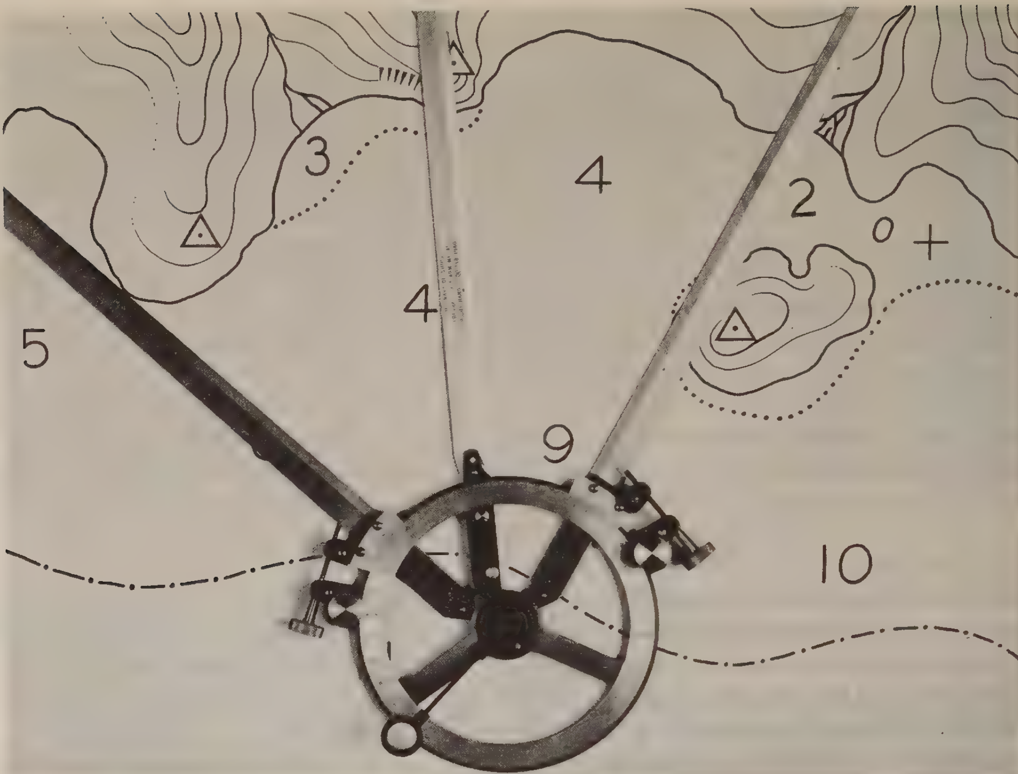

FIGURE 4011c.—Three-arm protractor.

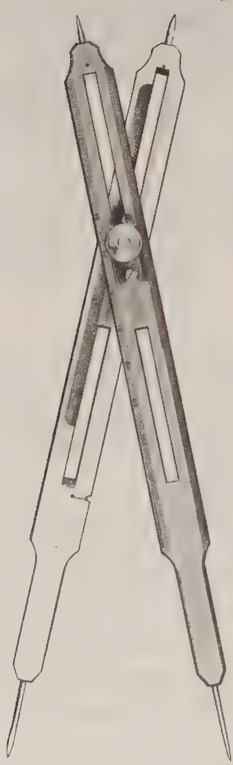

FIGURE 4011d.—Proportional dividers.

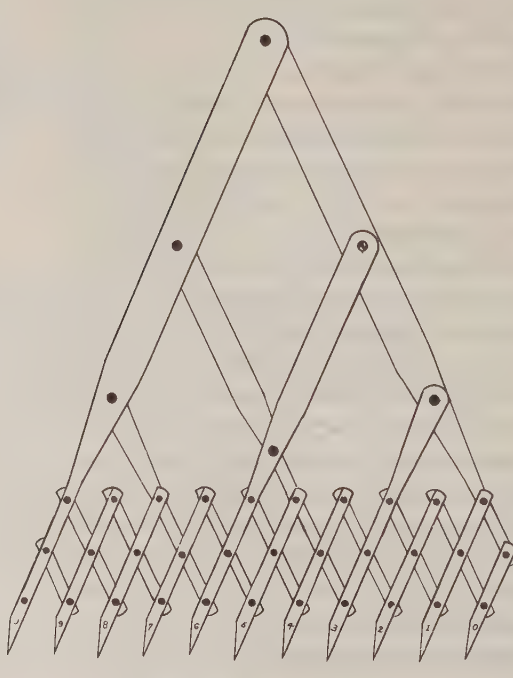

FIGURE 4011e.—Spacing dividers.

legs, each with a point at each end, and a movable pivot. When the pivot is at the middle, the two leg openings are equal. If the pivot is moved toward one end, the leg opening at that end is less than at the other, at a fixed ratio. The path of travel of the pivot is graduated so that a predetermined ratio can be set on the instrument.

Spacing dividers (fig. 4011e) are useful in subdividing distances into equal parts, such as spacing soundings along a line between two boat positions. They are designed so that as they are opened, the spaces between points are equal.

Other, commonly used drawing instruments such as scales, triangles, etc., are also used in chart work.

CHAPTER XLI

HYDROGRAPHIC SURVEYING

Introduction

4101. Hydrography is that science which deals with the measurement and description of the physical features of the oceans, seas, lakes, rivers, and other waters, and their adjoining coastal areas, with particular reference to their use for navigational purposes. The process of making the measurements upon which the description depends is called **surveying.** Precise determination and marking of positions on land, and accurate measurement of a reference direction and distance, taking into account the earth's curvature, constitute a **geodetic control survey.** Measurement of details of water areas and appropriate details of adjoining coastal areas is called a **hydrographic survey.** In addition to delineation of coast lines and location and measurement of submerged features, a hydrographic survey usually includes measurement of magnetic declination (variation) and dip, tides, currents, and meteorological elements. Limited surveys may be conducted to satisfy particular requirements. Before a hydrographic survey can be conducted, a geodetic control survey may be needed if available information does not provide adequate control of positions.

The principal objective of most hydrographic surveys is to obtain information on water areas and adjacent coastal regions, to serve as source material for nautical charts, sailing directions or coast pilots, and other nautical publications of value to the mariner. The results of the surveys are also used for planning harbor improvements and seaplane anchorages; for studies of silting and erosion, oceanographic features, and earth sciences; and for military defense projects.

Nearly 71 percent of the earth's surface is covered by water. Only a small part of this area has been adequately surveyed, and much of the land area has not been accurately measured. The changes caused by nature and man, and the continual increase in requirements of more precise and more nearly automatic systems and methods of navigation, render obsolete the charts or surveys once considered adequate. Consequently, the need for ever more accurate, more complete surveys continues, with no end in sight.

Surveys are usually conducted by personnel who have been given specialized training, and are provided with complete equipment. A modern survey ship is shown in figure 4101. Detailed information on the conducting of such a survey is given in Special Publication No. SP–4, *Hydrographic Office Technical Specifications for U.S. Naval Surveys and Supplementary Data;* and in U.S. Coast and Geodetic Survey Pub. No. 20–2, *Hydrographic Manual.* The purpose of the present chapter is to acquaint the mariner with the principles of surveying, to provide him with sufficient knowledge to conduct an exploratory survey (art. 4127) of a previously uncharted area, and to obtain and record in suitable form new data for the correction and improvement of existing charts.

4102. Planning a survey.—As in other operations, an efficient and adequate survey requires advance preparation. In addition to a knowledge of surveying, one should acquaint himself with the available information on the area. A study of all available charts, aerial photographs, and written material should be the first step. Work sheets or planning charts can be prepared showing the location of principal

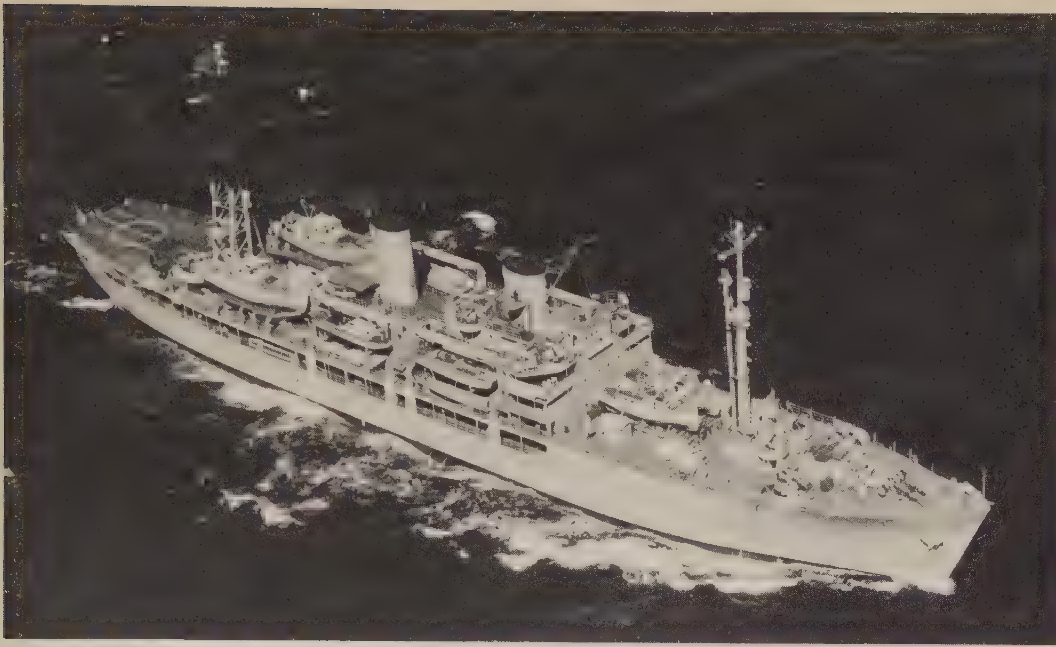

FIGURE 4101.—A modern survey ship, the USS *Maury* (AGS16).

landmarks; general configuration of coast lines; tentative anchorage areas, landing beaches, and camp sites; probable sites for the erection of signals to mark the various stations; and possible tide gage locations. Several copies should be made.

When the survey craft arrive at the area to be surveyed, several reconnaissance parties should be sent out to verify the information on the work sheets or planning charts. Tentative anchorage areas should be the first investigated. Protection during foul weather is essential to the safety as well as the comfort of the personnel who will man the small craft used for inshore soundings.

In the selection of landing beaches, safety of personnel and equipment is the primary consideration. Surf conditions, beach gradients, and bottom characteristics should be observed. The convenience of the locations and access to good routes of travel on shore are also important.

The selection of sites for signal marks should be made by an experienced surveyor, if one is available. Visibility from the sea is the most important consideration, but intervisibility among stations, or with those used for a geodetic control survey, are important to the accurate establishment of the positions of the stations. High points and conspicuous features of the terrain should be utilized to the fullest extent, not only for hydrographic control, but also as aids in controlling aerial photography. A helicopter is a valuable aid in making such a study, permitting rapid reconnaissance of the whole area.

Particular care should be exercised in the selection of a tide station. It should be located in a protected area where there is little wave action, but where access of sea water is adequate and representative of the area. A depth of at least five feet below the predicted lowest tide is desirable. The tide gage should be installed on a rigid structure, which may have to be constructed if one is not already available. Wharves are most frequently used, but the gage should be so located that it will not be damaged by operations in the area.

A decision will have to be made as to whether or not a geodetic control survey is needed and, if so, its extent.

Geodetic Control Survey

4103. Origin of survey.—An important requirement of a survey is to establish the position of each feature measured. The first step is to determine carefully the location of one reference point. This should be established as accurately as circumstances permit, for all other positions are located relative to this one point, called the **origin.** Any error in the origin is carried over to the entire survey.

If an accurate land survey has been made in the vicinity, the origin of the new survey might be determined with respect to the earlier survey, so that there will be no discontinuity between surveys. If this method is not available, an astronomical position is customarily obtained.

4104. Astronomical observations are made by the best method available. The most accurate available in the field is generally by astrolabe (art. 4002). Both latitude and longitude are determined by a single set of observations. If a direction theodolite (art. 4004) is used, latitude and longitude are determined separately and somewhat less accurately. If neither of these methods is available, position is determined by the best available means. However careful the measurement, all astronomical positions are subject to a possible error due to deflection of the vertical (art. 1610).

Surveyors generally time observations by means of a chronometer rated to sidereal time, and set approximately to GST. The chronometer error on GST is determined by finding the GST at the time of comparison (using the *American Ephemeris and Nautical Almanac*) and comparing this with the reading of the chronometer. Usually, the longitude of an assumed position is converted to time units and combined algebraically with the chronometer error (or correction) on GST to find chronometer error (or correction) on LST. Thus, if the chronometer is $8^m15^s.2$ *fast* on GST and the longitude is $5^h06^m23^s.4$ *east* (76°35′51″.0E), the chronometer is $4^h58^m08^s.2$ *slow* on LST.

For survey accuracy, the *Nautical Almanac* does not provide sufficiently precise data. The *American Ephemeris and Nautical Almanac* or other source should be used. If observations are timed by sidereal time, local hour angle is found by subtracting right ascension (art. 1426) from LST. Similarly, the sight reduction methods commonly used by navigators are not sufficiently precise for use in surveying. In general, only those computations necessary to the conducting of the survey are made in the field. All of the data should be sent to the appropriate government charting agency, where detailed computations are made to check and perhaps refine those already made, and to supply the additional answers needed for interpreting and utilizing the information. The important part of the field work is to make all measurements carefully and accurately, and supply all needed data, suitably labeled, so that the end products will be reliable. All measurements should be made to a higher order of precision than in ordinary navigation.

4105. Observation by astrolabe.—The astrolabe is set up and carefully leveled. Star lists are available to indicate the name and constellation, right ascension, magnitude, azimuth, and local sidereal time at which various stars will have the desired altitude, neglecting refraction. A body near the prime vertical should be observed first to provide a check on the local sidereal time, which is used for timing observations. As each additional star approaches the fixed altitude of the astrolabe, the observer picks it up and centers it in the lower power eyepiece. He then shifts to the higher-power eyepiece, and as the body reaches the fixed altitude, he presses a telegraph key, recording a mark on a chronometer-chronograph record tape. If available, about 100 celestial bodies are thus measured.

About ten or 12 of these stars, well distributed in azimuth around the entire horizon, are selected. The zenith distance of each star is computed for the time of observation. Computation is customarily made by means of the navigational triangle; assumed latitude, meridian angle, and declination of the body being known. With a good assumed position, the computed zenith distance of most bodies will be greater than that indicated by the astrolabe used (30° for a 60° astrolabe; 45° for a 45° astrolabe) because of refraction. The differences in zenith distances, computed minus assumed (30° or 45°), are plotted as distances in seconds of arc along the azimuth line of the body, from the assumed position. A negative difference is plotted along the reciprocal of the azimuth line. At the points so determined, lines are drawn perpendicular to the azimuth lines. These are lines of position. If they are accurate, they

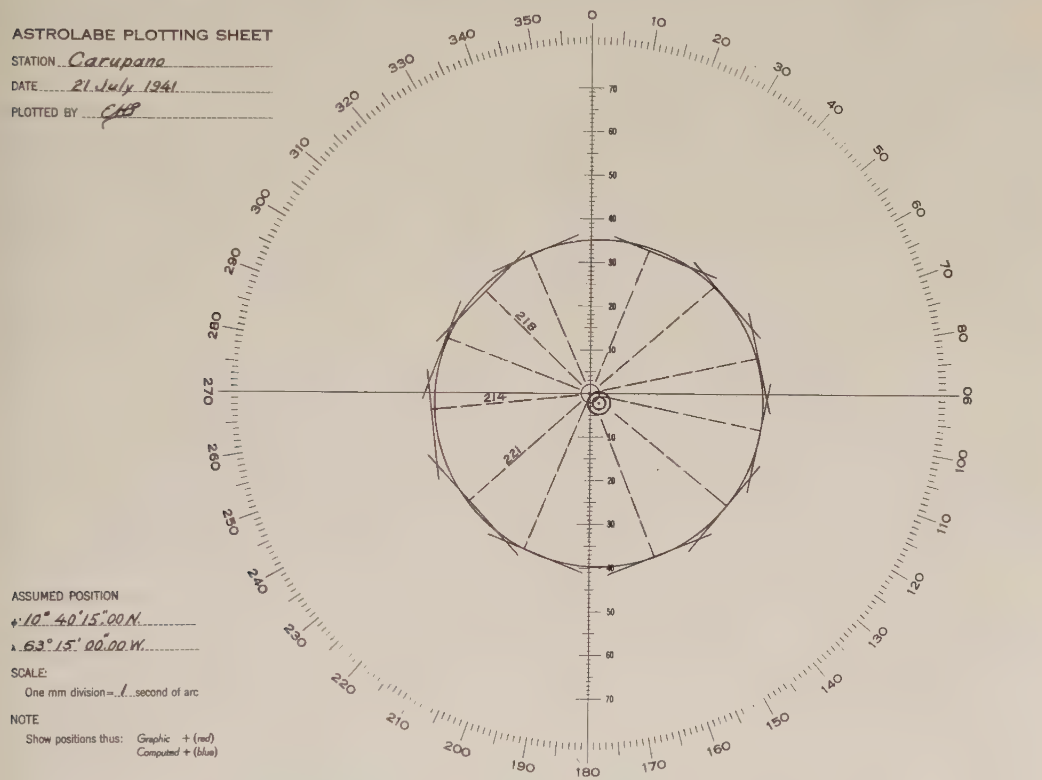

FIGURE 4105.—A typical plot of astrolabe observations.

are tangent to a circle which can be drawn within the figure formed by them. The radius of the circle is the constant error of observation, the principal component of which is refraction. The center of the circle is the position of the observer. Its latitude and longitude can be found by applying corrections to the assumed position. For highly accurate results, a correction is applied for convergency of the meridians. A typical plot of astrolabe observations is shown in figure 4105.

4106. Observation by direction theodolite.—When accuracy requirements are less exacting, as for a magnetic observation station, a position can be obtained in considerably less time by means of a direction theodolite.

Zenith distances of two stars are measured when they are within 5° of the prime vertical (one east, the other west) and their altitudes do not differ by more than 1°. If convenient, a minimum altitude of 30° should be used. Two sets of such observa-

tions are made, each observation being carefully timed. The meridian angle at the time of observation can be computed by time sight formula (art. 2106). This can be converted to LHA, which can then be compared with GHA to determine longitude. Surveyors generally compute local sidereal time and compare this with the Greenwich sidereal time of the observation.

The selection of stars near the prime vertical can be made by measuring the horizontal angle from Polaris or any other star near the meridian.

Latitude is determined from theodolite observations of northerly and southerly stars near the celestial meridian. In north latitude, Polaris is usually used for the northerly star. The two stars should have altitudes which do not differ by more than 1°, and should be within about 2° (azimuth) of the meridian.

4107. High-latitude observations.—The methods described in articles 4105 and 4106 are unsuitable in high latitudes because of the nearly-horizontal apparent motion of celestial bodies, and the continuous daylight during the summer, when surveys are customarily conducted.

The method usually employed is to set up a direction theodolite and observe the zenith distance of the sun at approximately hourly intervals. Timing is probably best done by means of a stop watch, which is started at the moment of observation and stopped at a convenient chronometer time shortly thereafter. Chronometer time at comparison minus the interval recorded by stop watch is the chronometer time of the observation. The chronometer should be checked by radio time tick immediately before and after observations, and the difference in chronometer error distributed evenly over the period of observation.

Local hour angle is determined and converted to meridian angle. With assumed latitude, declination, and meridian angle, the zenith distance of the sun is computed. This is compared with the observed value *corrected for refraction*. The difference is used to plot the line of position as in ordinary navigation. Since zenith distances are used, a greater computed value results in a *toward* situation. The navigator may find it less confusing to convert all zenith distances to the more familiar altitudes. If all observations and computations are completely accurate and the actual refraction does not vary from that used in the computation, all lines of position will intersect at a common point. However, this is rarely the case, and the center of the plotted figure is used, as in ordinary navigation.

4108. Direction.—A reference direction for a survey is established by carefully determining the angle between a meridian and the straight line connecting two prominently marked points. The angle is measured clockwise from *south*, as astronomers usually measure azimuth. This direction is determined at one of the marks by observation of the azimuth of a celestial body. The reference direction, which a navigator would call a "bearing" (measured from south), of the second mark from the observer is customarily referred to by surveyors as an "azimuth."

Azimuth is established by observation of a celestial body. A body having a nearly constant azimuth during the period of observation is the most desirable to use. In the northern hemisphere (except in very low or high latitudes) Polaris is ideal for this purpose. For maximum accuracy, it should be observed when it is at its greatest horizontal distance from the north celestial pole, for at this time its movement is most nearly vertical and the least change in azimuth occurs. If another body is used, it should be observed when its motion is most nearly vertical. A body that crosses the prime vertical should be observed when its meridian angle is 90°. For a body that does not cross the prime vertical (declination greater than the latitude of the observer, and of the same name), the desired condition occurs when the body is

nearest the prime vertical. This time can be determined by means of table 25, or by an inspection table such as H.O. Pub. No. 214. When H.O. Pub. No. 214 is used, the desired condition is indicated by a number of identical, or nearly identical, azimuth angles in consecutive entries in a column. The meridian angle at the most favorable moment can be converted to LHA, and this to GHA, which can be used with an almanac or the ephemeris to determine the time to make the observation (art. 2107).

Azimuth is determined by measuring the horizontal angle between the celestial body and the mark indicating the second place, using a theodolite. The azimuth of the celestial body is computed to the nearest 0″.1, and the horizontal angle is added (subtracted if measured counterclockwise from the body) to determine the desired azimuth. For best results, celestial bodies having low altitudes should be selected, if such are available.

A direction measured at the same point at which an astronomical longitude is determined is called a **Laplace azimuth.** Positions and directions at a second place, determined by a series of measurements of direction or distance, or both, do not, in general, coincide with values obtained by astronomical observation at the second station because of a difference in deflection of the vertical at the two places. The position as determined by a series of measurements from a "known" position is called a **geodetic position.** The geodetic azimuth differs from the astronomical azimuth by the amount of the **Laplace correction,** which is equal to $(\lambda_A - \lambda_G) \sin L_G$, where λ_A is the astronomical longitude, λ_G is the geodetic longitude, and L_G is the geodetic latitude. The accumulated error in a series of measurements is far greater in azimuth than in longitude. The Laplace correction, which assumes all the error is in the computed geodetic azimuth and none in the computed geodetic longitude, is applied to the astronomical azimuth at the second place to find the corrected geodetic azimuth.

4109. The base line.—Following the determination of a single accurate position and a reference direction, the length of a **base line** is measured, to serve as the basis for other measurements of distance. The length of the base line should be at least one-fifth that of the average side of the principal network of lines of the survey.

The length of the base line should be determined as accurately as equipment and conditions permit. For field surveys conducted by the U. S. Navy Hydrographic Office, the maximum error is specified as one part in 150,000. This is one foot in about 25 nautical miles, or about half an inch per nautical mile. The probable error (art. 2904) specified is one part in 500,000.

For such accuracy a carefully calibrated, low-expansion-coefficient, Invar tape is used under a standard tension which allows for sag and stretching. Corrections are applied for temperature, height above sea level, and inclination (if the ground is not level). With standard professional methods this accuracy can be obtained over moderately rough terrain with slopes up to 20°. The base line is divided into sections about one kilometer (a little more than half a nautical mile) in length. Each section is measured in each direction, using separate tapes, if available. It may be necessary to clear the line of brush or other growth to provide an unobstructed view. Stakes are driven at each tape length, and the distance between stakes is measured. A precise level (art. 4006) is used to determine the inclination. In making the measurement, care should be exercised to prevent kinks, abrasion, and tension greater than that prescribed.

The measurement of a base line can require a considerable amount of time. An approximate length can be determined quickly by means of a subtense bar (art. 4007) or even by a stadia, making the measurements in lengths of about 300 feet. Results obtained in this way are sufficiently accurate for graphic plotting done in the craft

running sounding lines. If later measurement indicates the need for adjustment, this can be provided by multiplying all distances by the ratio of accurate distance to preliminary distance. For a plot, only the *scale* need be changed.

If the survey covers a limited area, as a harbor, a single base line is sufficient. However, if the survey is to extend over a considerable area, additional base lines are needed as checks.

4110. Triangulation.—A network or chain of triangles with vertices at selected points on the ground is established in the area to be surveyed. In the selection of these points, which are commonly called **stations,** consideration is given to both topographic features and geometric factors. By carefully measuring the angles at the vertices of each triangle and using these measurements together with the position of the origin of the survey, and the length and direction of the base line, one is able to compute the position of each station. This forms a **triangulation net** (fig. 4110) covering the area and serving as the framework or skeleton to which all other positions are referred. The stations should be selected carefully to provide a strong net. This net, with its reference to the origin and observed azimuth, is called the **geodetic control** of the survey. Those control points which are used for fixing position during survey of the water area constitute the **hydrographic control.**

4111. Trilateration.—If a network of lines similar to a triangulation net is established by measuring the *length* of each line instead of the angles between lines, the process is called **trilateration,** and the system of lines is called a **trilateration net.** If lengths are measured by tape, as explained in article 4109, this is a time-consuming and often difficult or impossible process. However, with the development of electronic methods of measuring distance, trilateration became a practical method. In periods of low visibility, or where lines are too long for visual observation (as between off-lying islands and the shore), it may be the only method available.

4112. Traverse.—In some areas the best, or only available, method is by measuring both direction and distance of a series of lines. This is a **traverse.** It might be used where a clear view of one station is not available from others, or along an irregular beach. The application is usually limited, so that a traverse is generally somewhat subsidiary to the main triangulation or trilateration.

In planning a traverse, one should select a route affording reasonably long legs as free as possible from obstacles. When the traverse is used to connect two parts of a net, reciprocal directions should be measured at the two ends, to provide a check. This provides two routes by which a line of the triangulation or trilateration can be carried through to a line of the traverse. Where the traverse follows a route with many curves, as along a stream or beach, it should be connected to the main triangulation or trilateration net at several points. If this is not practicable, an azimuth line should be established between points several legs apart, so that directions can be carried forward with greater accuracy. All main traverse stations should be permanently marked, but intermediate stations need not be permanently established.

4113. Signals.—As each station is established, a conspicuous structure or **signal** is constructed or designated to mark the site. It is essential that the signal be accurately centered over the station, which for principal stations is marked by a bronze marker set in concrete. The signals take different forms depending upon the distance over which they are to be seen, obstructions, the need for identification, background, and the availability of existing structures. The shape, target area, and color are factors to be considered. The color is selected with particular reference to the background. The three types of signal most used for principal stations are:

Tower. A tower is used when needed to clear obstructions, where the distance is so great that the curvature of the earth is a consideration, or where a smaller target

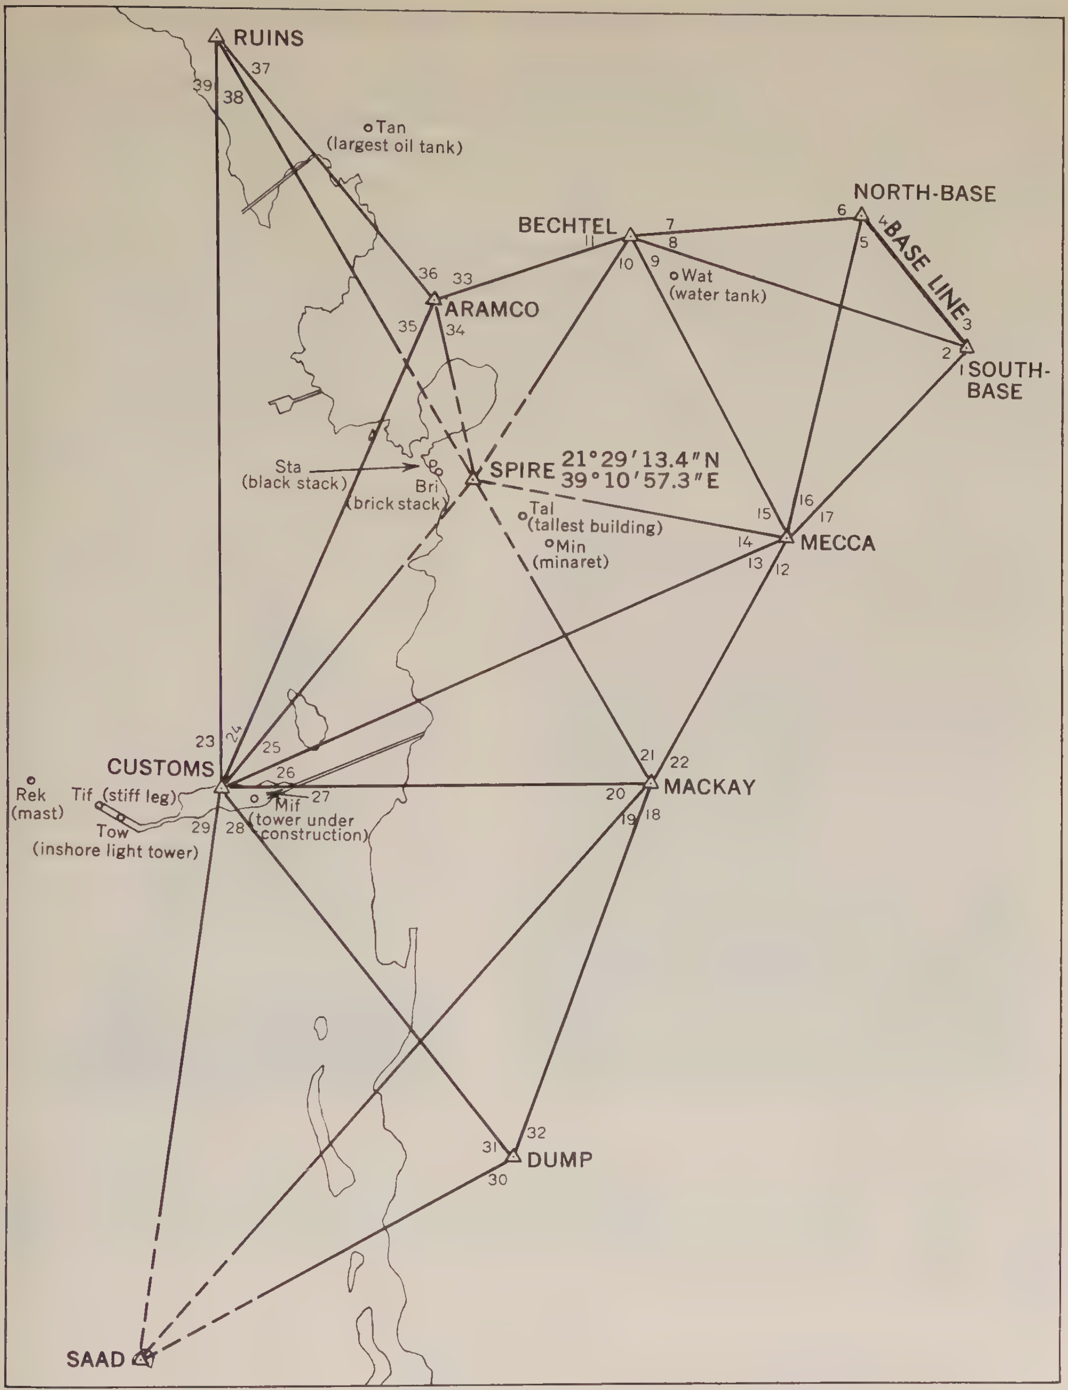

FIGURE 4110.—A typical triangulation net.

might not be sufficiently conspicuous. The type of tower generally used is an open-framework, prefabricated structure of galvanized steel, which can be assembled rapidly by an experienced crew (fig. 4113a). It consists of an inner tower to furnish instrument support, and an outer independent structure to support a platform for the observer. The tower is constructed in sections, to a maximum height of 113 feet. It can be made

smaller by omitting one or more of the bottom sections. Part of the outside may be covered with cloth to make it more conspicuous.

Tripod. A wooden tripod (fig. 4113b) is the signal used most frequently when the observer has good visibility from the ground. Usually, the lumber is cut aboard ship and assembled at the site. It is generally about 25 to 30 feet high and covered with cloth or provided with latticed lumber to make it more conspicuous. It is firmly anchored and guyed by wires as necessary.

Existing structures. Conspicuous church spires, chimneys, flagpoles, lighthouses, etc., can be used. For a complex structure, the specific part used should be specified. If there is any reasonable possibility of confusion, as when several chimneys are close together, the structure should be avoided. When an existing structure is used, a permanent marker is not installed. Usually it is necessary to observe from some point nearby, called an **eccentric point,** and provide a correction to the observations made from the station. This is done by measuring (1) the distance (D) between the structure

FIGURE 4113a.—A tower survey signal.

FIGURE 4113b.—A tripod survey signal.

and the point of observation; and (2) the angle (α), at the point of observation, between a line to the structure and one to another signal, at an approximate distance (s) from the site. The correction (C) in seconds of arc to be applied to the direction of the distant station observed is then

$$C=\frac{D \sin \alpha}{s \sin 1''}.$$

Secondary signals for intermediate stations may be improvised from any suitable material available. Examples are a single pole with cross-lattice work or a flag, a whitewashed tree trunk or rock, a whitewashed box or barrel filled with stones or earth and surmounted by a flag, a piece of sheeting wrapped around a bush, etc.

It is common practice to give each station a short name, for easy identification.

4114. Records.—It is of importance that measurements be made carefully, and that complete records be kept. Each observer should be provided with a notebook in which to make notes as the survey progresses. At the end of each period of observa-

tion these notes should be converted to good form for the permanent record of the survey.

All information should be evaluated as it is received. In many instances this requires at least preliminary computations to determine whether the work is of acceptable accuracy. Surveyors usually measure distances in meters to the nearest 0.01 meter and angles to the nearest 0.″1, and compute geodetic positions to the nearest 0.″01. In a triangle formed by survey lines, the three angles should equal 180° plus the **spherical excess** due to curvature of the earth. This amounts to about 0.″0175 per square nautical mile of area. If facilities are not available for computation, large-scale, carefully drawn plots may suffice. As the various positions are determined, they are plotted on a polyconic projection (art. 315). Any results that seem inconsistent with others should be measured again.

A complete description of each station, preferably with a sketch, should be prepared. It is generally desirable that preliminary descriptions be prepared independently by two observers, who should then collaborate in preparing the final description. This information may be needed if the station is to be reoccupied, perhaps many years later.

When a regular survey party is sent out, it is provided with standard computation forms, tables, and blank books for recording observations, as well as the instruments and other equipment needed to do the work. Others make the best use of whatever is available.

When the survey is completed, all of the records are forwarded to the government agency responsible for charting the area. For United States personnel, this is the U. S. Coast and Geodetic Survey for United States territory, and the U. S. Navy Hydrographic Office for foreign areas.

Hydrographic Survey

4115. Control.—Hydrographic surveys differ in several respects from geodetic control surveys. The surface of the water is relatively flat, and the water obscures vision of the relief of the bottom. As a result, sharp discontinuities in the bottom level, such as pinnacles, might escape detection. Permanent stations are not established at sea, and the lack of a stable platform precludes precision measurement of angles with the type of equipment used ashore. Measurement of distances by tape is impractical over water.

The principal function of a hydrographic survey is to determine depths of water. The positions at which soundings are obtained are determined by reference to established points on shore. In addition to locating the points at their correct geographical positions, this practice results in the land and marine features being in correct relationship to each other. This is an important consideration because the marine navigator near a coast also locates himself relative to the land, in many instances using the same landmarks used by the surveyor.

The means used for determining the position of the sounding craft is called **control.** The two kinds of hydrographic control in common use are **visual** and **electronic.** At great distances from the shore, celestial navigation might be used.

4116. Visual control is the determination of position by visual reference to conspicuous landmarks. The most commonly used method is to obtain horizontal sextant angles and plot the position by means of a three-arm protractor (art. 4011). This is called the **three-point fix method.**

Any conspicuous object which has been accurately located can be used. Geodetic control survey signals might be available. Natural objects such as prominent

trees or sharp mountain peaks are often used. Existing structures such as lighthouses and church steeples make satisfactory marks. When marks are not available at desired locations, a signal might be constructed. The type most commonly used is a single mast 20 to 30 feet high, to which three triangular skirts are attached at angles of 120° to each other (fig. 4116). A flag of distinctive color may be attached to the top to aid in identification. Floating signals may be used in shoal areas to extend control beyond the limits of shore visibility. The signal generally used consists of a mast provided with skirts or wooden slats, and supported on an anchored floating structure. The location of such a signal should be checked frequently, as it might be displaced by wind and wave action.

FIGURE 4116.—A single mast survey signal.

The distance between signals depends upon the scale of the survey, general contour, and visibility. In general, signals should be one-half to one mile apart for harbor and anchorage surveys, and one to two miles apart for coastal surveys.

The signals used for hydrographic surveys are normally positioned by reference to geodetic control survey stations. This is usually done by one of the following methods:

Intersection of bearing lines from three or more stations, the position being determined either by computation or plotting.

Resection by observing the bearing of three or more stations from the position to be determined.

Traverse from established stations.

A "ship-shore" method is occasionally used. Horizontal sextant angles between the signal to be located and an established point are observed aboard ship at the same instant that the shore party measures angles from known points to locate the ship.

4117. Electronic control is used in periods of low visibility, and beyond the range of normal visibility from shore. Any electronic positioning system meeting the accuracy requirements might be used. Those which have been extensively used are radio acoustic ranging (art. 1205); radar (art. 1208), usually with transponder beacons (art. 1108); shoran (art. 1213); electronic position indicator (art. 1213); Lorac (art. 1310); Decca (art. 1309); and Raydist (arts. 1214, 1311). Radio acoustic ranging, electronic position indicator, and radar are no longer in common use for control.

To provide survey accuracy, the electronic equipment should be accurately tuned and calibrated, and should be operated within the closest practicable tolerances.

The direct ranging methods (radio acoustic ranging, radar, shoran, and electronic position indicator) provide results that can be used without special equipment. Ranges are usually plotted by means of a number of concentric circular arcs drawn in advance on the plotting sheet, or in some cases by means of a beam compass and a diagonal metric scale (art. 4011). The accuracy of such readings varies with conditions, but about the best that can be expected for single readings is 15 yards for shoran, 75 yards for electronic position indicator, and 150 yards for radar with transponder beacons.

The hyperbolic systems (Lorac, Decca, and Raydist) require location of the hyperbolas. These are plotted at intervals, and intermediate values are obtained by interpolation. The accuracy of these systems varies with position relative to the transmitters, but is sufficient for offshore surveys.

4118. Plotting sheets.—When the approximate extent of the area to be surveyed has been determined, a master plotting sheet is prepared, usually on the polyconic projection (art. 315). The scale depends upon the contour and the amount of detail to be shown. As the various items of information are determined, they are plotted on this survey sheet. Smaller sheets are prepared for use of the parties conducting the survey. Close to the beach these are of the same scale as the master sheet, but farther out they may be of smaller scale. These smaller sheets may be called **boat sheets, ship sheets, shore line sheets,** etc., as appropriate.

4119. Topography.—The positions of the shore line, streams, mountains, hills, etc., may be available from a land survey. If this information is not available, it is determined as part of the hydrographic survey.

The position of the shore line is best determined by means of vertical aerial photography (ch. XLIII). If this method is not available, positions are obtained, usually by horizontal sextant angles, at short intervals along the beach. The beach line is sketched in through the established points.

Inland features are located by horizontal sextant angles or by transit angles from triangulation stations. The heights of hills near the shore can be determined by vertical angle measurement and table 9 (or more accurately by computation), or by difference in the reading of a barometer, using table 11 or the formula of article 3707. If enough information is available, contours should be sketched in. The location of a summit should be indicated by a dot, and the height indicated by a number.

4120. Hydrographic features.—Depth is determined by running a series of parallel **sounding lines.** Usually, these are run normal to the general trend of the beach, but in areas of shoals or other dangers, they should be run in such direction as to provide the best indication of the bottom features. The sounding lines should be spaced at intervals of two-tenths of an inch on the plotting sheet. Check lines should be run perpendicular to the main group, at intervals of perhaps two inches on the plot. When these sheets are prepared, the desired lines should be drawn lightly in pencil to serve as a guide to the sounding craft. Bottom samples should be taken at intervals of not more than two inches on the plotting sheet, except in depths greater than 50 fathoms, where bottom samples normally are not taken unless required for the oceanographic aspects of the survey.

In shoal water and sheltered areas, sounding lines are run by small craft. Farther from shore larger craft, including the survey ship itself, run the lines.

For harbor and anchorage surveys, the scale of the plotting sheets is generally 1:5,000, 1:10,000, or occasionally 1:25,000. A fix should be obtained every two minutes. Soundings should preferably be obtained by a recording echo sounder, to provide a bottom profile. Every 15 seconds the sounding should be recorded in a **sounding book** provided for this purpose. If the depth is not greater than 11 fathoms, soundings should be recorded to the nearest foot. For greater depths, the nearest one-half fathom is sufficient.

For channel surveys, the scale of the plotting sheet may be 1:10,000, 1:25,000, or even 1:50,000 in some cases. Fixes should be obtained at intervals of two minutes, and soundings recorded every 15 seconds unless the scale of the survey is 1:50,000, when every 30 seconds should suffice.

For coastal surveys, the scale should be about 1:50,000 to a depth of 20 fathoms, 1:100,000 between 20 and 100 fathoms, and 1:250,000 for greater depths. The interval between fixes should be about three, five, or ten minutes, respectively, for the three scales. Soundings should be recorded every 30 seconds for a 1:50,000 plot, and every minute for smaller scales.

Sometimes it is necessary to sound an area well offshore, as a bank in the open sea. The individual circumstances govern the choice of technique to use. Control is provided by the best means available. If the area is beyond the range of the electronic position indicator, celestial navigation or loran might be used. If the water is sufficiently shoal to permit anchoring, a relatively large number of observations might be made to establish one position from which others can be determined. Open ocean surveys are further discussed in chapter XLII.

In any hydrographic survey, an area in which the existence of a shoal or other obstruction is suspected should be sounded thoroughly by a number of closely spaced lines, to be reasonably certain that the least depths have been found and their positions accurately determined. The surest way of determining that the least depth has been found is to use a **wire drag.** This is particularly important in rocky or coral areas, where individual pinnacles may not be found by sounding, however thorough. Basically, a drag consists of a submerged horizontal "ground wire" suspended by upright wires from buoys and held at a constant depth by weights and submerged floats. The ground wire is towed over the area between two vessels, and will strike or *hang* on obstructions extending above the depth at which it is towed. If the ground wire rides up over the obstruction, the fact is indicated by the falling over of the supporting buoys. The depth at which the ground wire is towed can be varied by altering the length of the upright wires. The depth usually used is 42 feet. The wire drag was developed by the U. S. Coast and Geodetic Survey. A detailed description of the construction and use of the device is given in Publication No. 20–1 of that organization. Since wire drag surveys are costly and time-consuming, they are normally used only in critical areas such as important harbors, anchorages, and channels.

A pier and its surrounding area should be surveyed carefully. Its direction and dimensions should be established accurately. Hand lead soundings should be taken every 20 feet along the face of the pier. Additional sounding lines should be run parallel to the pier at distances of 20, 40, and 60 feet.

In general, a small stream is sufficiently surveyed for chart purposes if a few lines of soundings are run in the navigable part, parallel to the principal reaches, with an estimate of the distances to each shore. However, individual circumstances should govern.

4121. Tide and tidal current observations.—Tide observations should begin as soon as practicable, using the appropriate equipment (art. 4009). A permanent tide station may be installed, but more often temporary stations are used in surveying. If the area to be surveyed is extensive, or if local conditions indicate a possible wide variation in tidal conditions at different points in the area, several stations should be established at representative points. Observations should continue throughout the period of the survey, or longer if practicable. It is desirable that the period of observation extend over an entire synodical month (29½ days).

A sufficient number of tidal current observations should be made to establish the current pattern for the area, with particular reference to the direction and maximum speed in the principal channels, and the times of all maximum speeds and slacks.

If a current meter (art. 4010) is not available, observations can be made by an improvised method. A **current pole** consists of a pole weighted so as to float vertically, and having a **log line** attached. The pole is placed in the water from an anchored vessel or fixed point, and permitted to drift with the current. The amount of drift in a timed interval can be determined by measuring the length of line paid out. A simple computation can be used to convert this to speed. The direction can be determined by noting the direction the log line tends. This method is particularly adapted to current measurement at the anchorage of the survey ship. In the channels, a

launch can be permitted to drift with the current, its position being determined at short intervals by horizontal sextant angles and three-arm protractor, or other suitable method. Occasionally, current can be measured by water-soluble dyes.

4122. Magnetic measurements.—If specialized magnetic instruments are available, a magnetic observatory can be set up ashore to determine all magnetic elements for which equipment is available. Observations might continue throughout the period of the survey. If such equipment is not available, a magnetic compass might be taken ashore, free from the deviating influence of the vessel, and the variation determined by carefully measuring the magnetic direction of any accurately measured line of the survey. If no such line is available, magnetic azimuths of the sun or other celestial body can be measured and compared with the computed true azimuth at the same instants. A dip needle might be available to measure the magnetic dip.

It is desirable to take readings at a number of places, to check for anomalies. In the water areas, anomalies which affect variation can be detected by steering a steady course and measuring the compass bearings of established shore points from a series of known positions as the vessel proceeds. These can then be compared with computed or measured true directions to determine compass error, which should remain essentially constant as long as the course remains unchanged.

At the principal shore station, observations should preferably continue over the period of the survey, to eliminate the effects of any magnetic disturbances. Because of possible diurnal change, readings should be taken at different times during the day. If this is not practicable, readings are best made at about noon.

4123. Geographic names.—The correct names and spellings of all named places and features in the area covered by the survey should be determined from reliable local sources, noting any established variations. Full information on names should be submitted with the survey records.

4124. Aids to navigation.—The location of each aid to navigation should be determined carefully. A description of the aid should be prepared and, if lighted, its characteristics should be timed. Any discrepancies between actual conditions and information given in the light lists or sailing directions should be noted. The prominence of the aids with respect to their backgrounds should be observed, and any advisable precautions with respect to the aids should be recorded. Lines of demarkation between color sectors should be measured carefully. The directions and lengths of ranges should be measured. If aids are moved from time to time because of changes in hydrographic features or seasonal ice or weather conditions, detailed information should be recorded. Signal stations and other prominent landmarks which might be useful to a navigator should be located and described.

4125. Miscellaneous information.—In addition to the various measurements, descriptive information forms an important part of a hydrographic survey. This is useful in the interpretation of the measurements, and it provides a major source of information for notes on the charts, and for compilation of sailing directions or coast pilots. The amount and detail of the information to be collected varies with individual circumstances. The surveyor should be alert to note any items that should be included, recording the appropriate details as they come to his attention. Even negative information is helpful when it answers a question that might logically come to the mind of the mariner. Examples of the items that might be included are:

Errors, omissions, or ambiguous statements in publications such as sailing directions or light lists.

A description of the general trend, features, and aspect of the coast as it is approached. This description might well be supplemented with pictures or radar scope photographs from stated positions and heights.

The color and extent of discolored water.

The nature and extent of meteorological and seasonal influences.

The kind and type of ice.

The location of fishing stakes, nets, and fishing boat operations.

The location, landing places, and shore markers of submarine cables; and the location and height of overhead cables.

The location of ferry crossings and other areas where local traffic may be heavy.

The location of restricted or military operating areas, with a statement of the regulations pertaining to them.

The location and extent of overfalls, rips, etc.

A description of the various awash dangers at various stages of the tide.

The location and nature of all wrecks, with all pertinent information regarding their visibility, depth, markers, etc.

Whether or not channels are dredged, and the probability of their filling with sediment.

Safe speed to use through channels, confined waters, etc.

Suitability of anchorages with respect to holding qualities, availability of mooring buoys, freedom from obstructions, direction and speed of wind and currents, amount and direction of swell, etc.

Location and description of special anchorages, with the regulations concerning their use.

Prevalence of fog and other visibility-limiting phenomena.

Any needed explanatory information on tides and currents.

The appearance and effect of mirages, abnormal refraction, phosphorescent seas, etc.

Local harbor regulations.

Port and aerodrome facilities.

Pertinent information regarding shore settlements.

4126. Records.—As information is collected, it should be evaluated and incorporated in the one master record. Each item should be verified as it is recorded. When the survey has been completed, the smooth copy of the completed information should be sent to the appropriate government charting agency. When an acknowledgement of the receipt of this information is received, the additional records such as sounding books, angle books, etc., should be forwarded.

Limited Surveys

4127. Exploratory survey.—When time or lack of equipment does not permit, or where desired results do not justify the carrying out of a standard geodetic control or hydrographic survey, a limited exploratory survey may be conducted. This might be an advance investigation to determine the desirability of making a full detailed survey, an operation to make a preliminary chart of an anchorage, an investigation of a reported shoal, etc. The principles and techniques in general conform to those described earlier in this chapter, but are adapted to meet the requirements, instrument limitations, and training of personnel. This is the type of survey that might well be assigned to a nonsurvey vessel.

When the area to be surveyed is covered by maps or charts of reasonable reliability, it is customary to establish the origin of the survey by scaling the position of one landmark from the chart. When this source of information is not available, the origin might be determined by careful measurement of electronic or celestial information needed for a position. If the position is determined from celestial observations ashore,

a theodolite or transit should be used if available. If it is not, an artificial horizon might be used with a sextant. It is desirable to observe at least 12 bodies well distributed around the horizon. At sea, it is desirable to anchor, or remain in the vicinity of an anchored aid to navigation.

A reference direction is best determined by astronomical means. If a theodolite or transit is not available, a sextant might be used with a body at low altitude, measurement being made of the horizontal angle. If visibility limitations or available time does not permit, a gyro compass might be used, as follows: With the ship at anchor, bearings of an observer on shore are observed. The observer measures the horizontal angle between the ship's gyro repeater used for the observation, and a landmark, using a theodolite, transit, or sextant. The reciprocal of the gyro repeater bearing, with the measured angle applied, is the direction from the observer to the landmark.

If the length of the base line cannot be measured by one of the methods described in article 4109, an approximation of sufficient accuracy for some purposes might be determined by measurement from the ship, using any available means, such as radar. Either of two methods might be used. A base line across navigable water might be selected. As the ship steams across the base line the distance to each shore station is measured. The least sum of the two distances is the length of the base line. The average of several such determinations should be used. By the second method, the distance to a single shore station is measured. At the same moment, an observer at the shore station measures the angle between the ship's radar antenna and a second shore station. At the second station an observer measures the angle between the antenna and the first shore station. With this information, the length of the line between the two shore stations can be computed.

If triangulation is needed, it is carried out as accurately as time and equipment permit. If horizontal sextant angles are used, the stations should be at nearly the same height if practicable.

An essential part of an exploratory survey of a harbor or anchorage is to delineate the shore line and coastal topography as accurately and completely as time permits. The quickest and best method is to use vertical aerial photography, if available. If this is used, established control points should be marked and described. If this method is not available, a reasonably accurate method is to run a traverse along the beach. A quick method of obtaining a rough approximation consists of determining radar bearings and distances to a number of shore points, from an anchored ship, and sketching in the shore line. A photograph or trace of a radar PPI presentation is another possibility.

Heights might be determined by transit or sextant angles, or by air search radar, with table 9.

Sounding lines are run as close together as conditions and time permit. Fixes are obtained by horizontal sextant angles, cross bearings, or radar at such intervals as warranted by the requirements of the survey and available time and equipment. Fixes at three-minute intervals are commonly used in harbor areas. The position of a sounding boat might be determined relative to the anchored survey ship, using radar. The sounding lines should be run in a systematic manner, with shoal areas being given extra attention. Soundings should be plotted directly on the work sheet, and fathom curves sketched in as the information becomes available.

Tide and current observations should be made as completely as time and conditions permit. A tide staff is usually used with half-hourly readings of the height. Current is usually measured by an improvised current pole (art. 4121).

A complete and accurate record should be made and forwarded to the appropriate government authority upon completion of the work.

4128. Running survey.—A limited survey can be conducted as a ship steams along a coast. The position at the beginning of the run is determined as accurately as conditions permit. If accurately charted landmarks are not available, it may be possible to send a landing party ashore to establish a good astronomical position.

As the survey progresses, the ship steams at a safe distance from the shore, determining its courses and speeds as accurately as practicable. Natural ranges may be available from time to time to provide good courses. If charted shore objects are available, frequent fixes can be determined and the dead reckoning between them adjusted to avoid gaps in the plot. As the ship proceeds, continuous soundings are taken, preferably by a recording echo sounder. Bottom samples are taken at frequent intervals if conditions permit, and if required.

If the shore has not been accurately surveyed and charted, positions of various prominent landmarks are established by a series of horizontal sextant angles or bearings, or by radar, as the vessel proceeds. A minimum of three readings should be made on each object, so that its plotted position will be reasonably accurate, and to be sure of identification. Since errors in this method are cumulative—the positions of landmarks being established from the ship, and then future positions of the ship established by means of the same landmarks—it is desirable to make all measurements as accurately as practicable. Generally it is best to steam at moderate and constant speed, stopping only if this contributes to the establishment of better positions.

If available, one or more launches might proceed along parallel courses between the ship and the shore to obtain additional lines of soundings. Their positions might be determined by a series of bearing and distance measurements, as by radar, or whatever means are available. These launches can collect additional information regarding the shore line and beach topography. Under some conditions a launch might contribute most to the survey by proceeding at will, obtaining angles and making sketches and notes, rather than taking soundings. With a recording echo sounder it might serve both functions.

All observations should be recorded, and all positions plotted as soon as received, so that apparent errors might be corrected while the landmarks are still visible. Because of the approximate nature of the survey, a large scale plotting sheet is not justified, a scale of 1:100,000 usually being adequate. Sketches and descriptions of various details along the coast can serve useful purposes later. If shore parties are landed, distinguishing marks might be established at some points. The amount of detail recorded depends primarily upon the time available, and perhaps upon the requirements of the survey. Discrepancies are certain to occur. These are resolved as accurately and completely as available information permits.

4129. Beach survey.—The most common purpose of a beach survey is to provide preliminary data for use in planning the constructions of piers, docks, or other harbor facilities. Another common purpose is to obtain data useful for landing supplies, equipment, and personnel directly on the beach from landing craft or amphibious vehicles.

Since a beach survey seeks detailed information about a relatively small area, accurate control (position) is essential. Several methods are in use:

Range and distance. Several ranges are established on shore, accurately measured by transit and tape, and marked by suitable markers. These ranges are established perpendicular to the general trend of the coast, and numbered for identification. The sounding boat runs lines of soundings in line with the ranges, determining distance offshore by stadia (with the rod in the boat and the observer on shore), or by attaching a line to an object on the beach and streaming out the line as the boat proceeds along the range, away from the shore.

Two ranges. Where the trend of the beach permits, two series of ranges can be established nearly perpendicular to each other, so that distance measurements are not needed.

Two transits can be set up at accurately determined positions on shore. Angles to the sounding boat are observed simultaneously at frequent intervals. This method is precise, but does not provide guidance to the sounding boat, since positions are determined on shore at a later time.

Horizontal sextant angles can be determined simultaneously by two observers in the boat, the results being plotted by three-arm protractor. This method is not attractive unless the area to be sounded is extensive.

Depth of water may be determined by echo sounder or pressure gage where practicable, but generally soundings close to the beach are made by hand lead or sounding pole. If the bottom is very soft, the lower end of the lead or pole should be fitted with a disk to prevent excessive penetration.

Chart projections are seldom required for a beach survey. A plane coordinate grid oriented with respect to an origin on shore, or the ranges, is sufficient for most purposes. The scale should be appropriate to the area and accuracy requirements, 1 inch=100 feet being commonly used. Soundings should be recorded to the nearest one-half foot out to the depth considered critical for the project.

Tide observations should be recorded continuously during the survey and, if practicable, should be extended to cover a synodical month (29½ days). One or more permanent bench marks should be established, and the height of the water level determined relative to the nearest foot mark if a tide staff is used.

Current measurements should be made to determine any current along the shore, and also maximum ebb and flood.

If the beach is to be used for landing vehicles, the suitability of the beach and backshore for landing and operating the type vehicles involved should be determined by inspection and also by penetration and other tests, as practicable. Wind, sea and swell, coastal currents, and character of beach materials are factors which govern possible sedimentation or erosion, and so should receive attention in the survey.

If the sea approaches have not been surveyed, these areas should be given attention in connection with the beach survey.

4130. Bathymetric survey.—Sounding lines run at sea are of assistance in adding detail to existing charts, or in constructing special charts to serve particular purposes. Most of the required information is obtained by ships proceeding between ports, either singly or in company with other ships. The important factors are accurate depths and accurate positions. These operations are given more detailed attention in chapter XLII.

4131. Checking accuracy of existing charts.—A mariner can perform a real service to himself and others by being continually alert to detect errors on the charts or in sailing directions. When such errors are suspected, an *opinion* that an error exists, or the submission of a chart with corrections shown, is of relatively little value to a charting agency. Chart requirements demand a higher order of accuracy than that of a vessel fixing its position by normal methods of navigation.

Positions of shoals, aids to navigation, landmarks, etc., should be determined carefully by whatever method is available. The average ship is provided with means for determining position to accepted accuracy. For instance, if an uncharted shoal is found, a launch should be sent to investigate. A sounding lead, two sextants, a chart, a three-arm protractor (improvised if necessary), and plotting board may be all that is needed. As the launch moves back and forth across the shoal, soundings are taken and simultaneous horizontal sextant angles between conspicuous charted objects are meas-

ured. If a single sextant is available, angles may be measured in quick succession, followed by a second measurement of the first angle, at approximately the same time interval as that between the first two measurements. If the objects are at a considerable distance, so that angles change slowly, the average of the two readings of the first angle can be used without significant error. Positions are then plotted and soundings recorded. The height of tide should be noted by tide table or other available means. The investigation should be continued over a sufficient area, and with enough thoroughness, to obtain an accurate indication of the nature and extent of the feature. If time permits, the surrounding area should be investigated to determine other possible shoals.

Points on land might be located by a number of bearing or distance measurements from different accurately located positions of the ship, or by measurements of direction made on land. A new structure might be located by information obtainable ashore, or by reference to other nearby structures. If a charted landmark is missing or has been moved, information should be sought ashore to determine the permanency of the change, and perhaps precise information regarding position, height, etc.

The number of variations is almost limitless, but the important thing to remember is the need to be alert to detect possible errors in the chart, and to obtain as complete and accurate information as practicable, submitting all details and an evaluation of the reliability of the data submitted. If complete information is not available, send what can be obtained, to at least alert the charting agency of the need for a correction. In the case of man-made changes, a possible source of complete information is helpful if the data itself cannot be obtained.

The mariner himself is one of the most valuable sources of information. By providing reliable data, he can help keep his charts and sailing directions accurate, current, and complete.

CHAPTER XLII

OCEANIC SOUNDINGS

4201. Introduction.—Relatively little is known of the surface features of the nearly 71 percent of the earth covered by water. However, enough has been learned to indicate that the unseen topography beneath the oceans has all the features common to that above water. It is known that there are submerged mountains extending to greater heights above their surroundings than do the Rockies, and depressions deeper than the Grand Canyon.

While many of the general features are known, details are lacking. A very large number of accurately located soundings are needed to provide sufficient information to

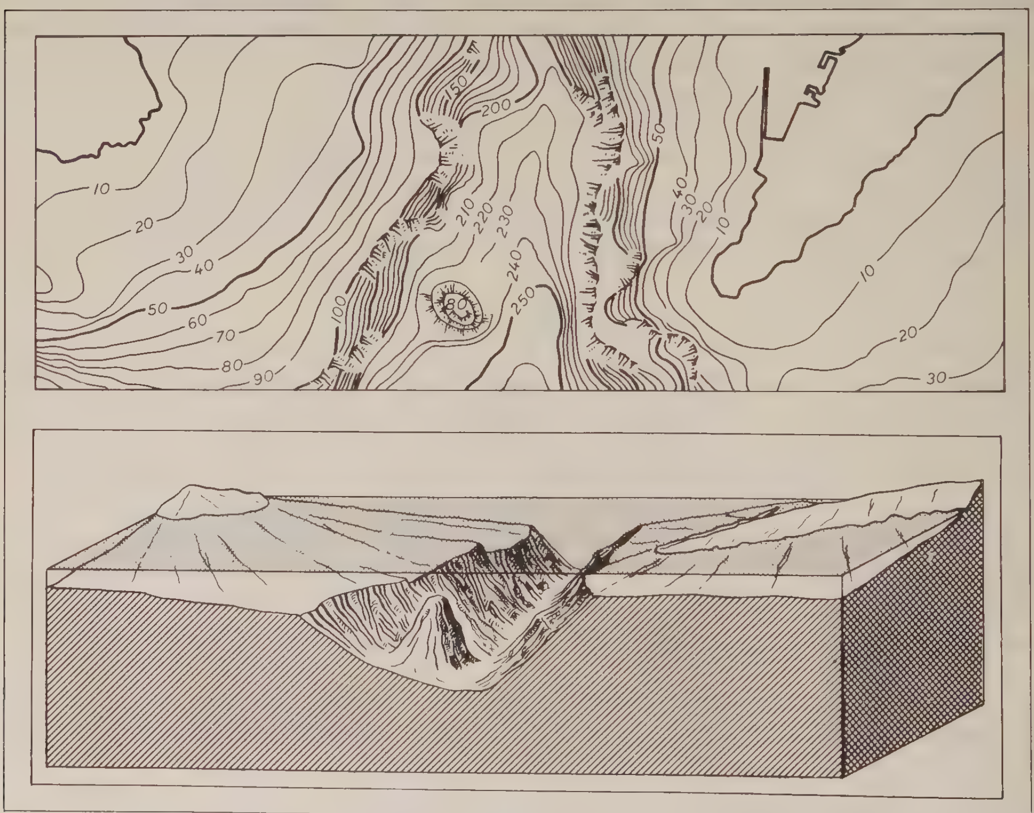

FIGURE 4201.—Contour lines and hachures (top) may be used to show underwater relief (bottom).

describe adequately the underwater relief. If sufficient information is available, such relief can be delineated on nautical charts by means of contours and hachures. A simplified chart of this type is shown in the upper part of figure 4201. The lower part of the figure is a block diagram of the area shown on the chart. Only a small part of the oceans has been sounded sufficiently to provide the detailed information needed for such a chart. Even in narrow strips along many coasts, along the route of the North Atlantic cable, and along a strip of the Pacific from California to the Carolines, where

soundings have been most numerous, the underwater relief is not known with the desired completeness and accuracy.

As long as oceanic soundings could be made only by a vessel stopping and lowering a weight, a process which might require several hours for a single sounding in very deep water, it was impractical for most vessels to obtain very much depth information at sea. With the development of the echo sounder, however, this situation has changed. With a recording echo sounder, a ship can obtain a profile along its track from continent to continent without slowing, using about a yard of recording paper per day. Such information, if reliable, is of great assistance to charting agencies in preparing more adequate charts of the ocean areas.

4202. Sounding equipment.—While lead lines and sounding machines have been used at sea, almost all deep-sea soundings are now taken by echo sounder (art. 619). If a depth recording device is available, it should be used, as the profile thus produced is a better indication of the bottom than even the most closely spaced visual readings.

All echo sounding equipment is subject to certain errors unless the operator has a clear understanding of the operating characteristics and limitations of the instrument. The routine checks recommended by the manufacturer should be made at every change of the watch, or oftener. In addition, the operator should be alert for certain possible errors peculiar to his instrument. A close watch should be kept on the proper functioning of the stylus, recorder speed, the zero adjustment, and the frequency of the electric current. The percentage error in the recorded depth is the same as that of the electric current frequency. Thus, at 3,000 fathoms, the error of a 60-cycle echo sounder is 100 fathoms if the actual frequency is in error by two cycles.

4203. Evaluating results.—Inaccurate results may be worse than no information at all. Therefore, every effort should be made to obtain reliable data. Particularly, soundings which conflict with known or charted depths should be carefully analyzed. Even when the equipment is operating correctly, false returns might be received due to sources external to the vessel. A shoal "phantom bottom" may be due to marine life, there may be multiple echoes or interference, or no return may be received because of aeration of the water or suspended matter in it. Such errors are further discussed in article 3504. Unusual local conditions may be a source of error. If an error is believed probable, but no source is detected, full information should be submitted with the soundings, for the charting agency may be able to interpret the results. This action is particularly important where the measured depths are less than those shown on the chart. If no error can be found, the charting agency may have no alternative but to enter the shoal soundings upon the charts affected, and take the first opportunity to send a survey vessel to verify or disprove them.

The speed at which sound travels in water varies with the salinity, temperature, and pressure. When these are known, corrections can be applied to obtain more accurate results. However, this is normally done only for scientific purposes Those soundings submitted to a charting agency should be the uncorrected values obtained by using an assumed standard speed of 4,800 feet per second.

4204. Deep sea sounding lines.—Most deep sea soundings are obtained by ships proceeding between ports. Soundings should be taken at every opportunity. Those taken in well-surveyed areas can be of assistance to the navigator in locating his position. If they conflict with values shown on the chart, and no error is found, they should be sent to the appropriate charting agency, with full particulars. All soundings in areas for which little depth information is shown on the chart should be submitted.

In addition to reliable soundings, accurate positions are needed. Navigation should be in accordance with standard practice, using every practicable means to reduce error and provide frequent checks on position.

When two or more ships are operating together, they should steam on parallel courses about five miles apart, maintaining stations abeam of each other by continuous monitoring by radar and pelorus, or other available means. Only one ship should perform the navigation used for controlling the survey.

4205. Investigating small areas.—If a feature of particular interest, such as an isolated shoal or a seamount, is found or reported in the vicinity of the vessel, a service can be rendered by conducting a further investigation in the vicinity of the feature. Two methods are in common use for this purpose:

Radial. A system of radial lines 20° apart are laid out from a central control point, preferably at the center of the feature to be investigated. These are extended outward for a distance of about 30 miles, and the ends of alternate ones are connected, as shown in figure 4205a. These form a series of course lines as shown.

Parallel. A north-south, east-west square is laid out with perhaps 60-mile sides, the center of the feature of interest being at the center of the square. A series of course lines are drawn parallel to one side of the square, at intervals of about five miles. The ends of alternate parallel course lines are connected, as shown in figure 4205b.

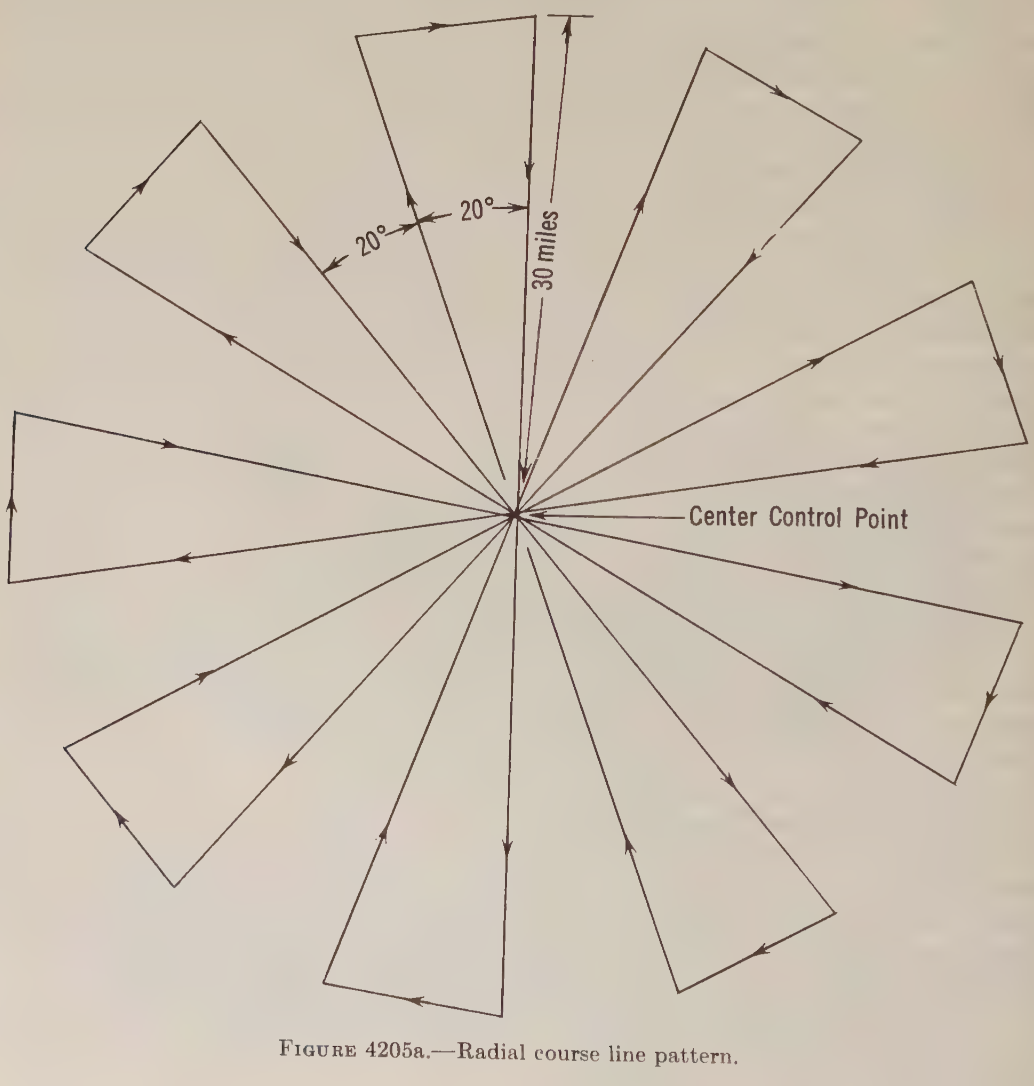

FIGURE 4205a.—Radial course line pattern.

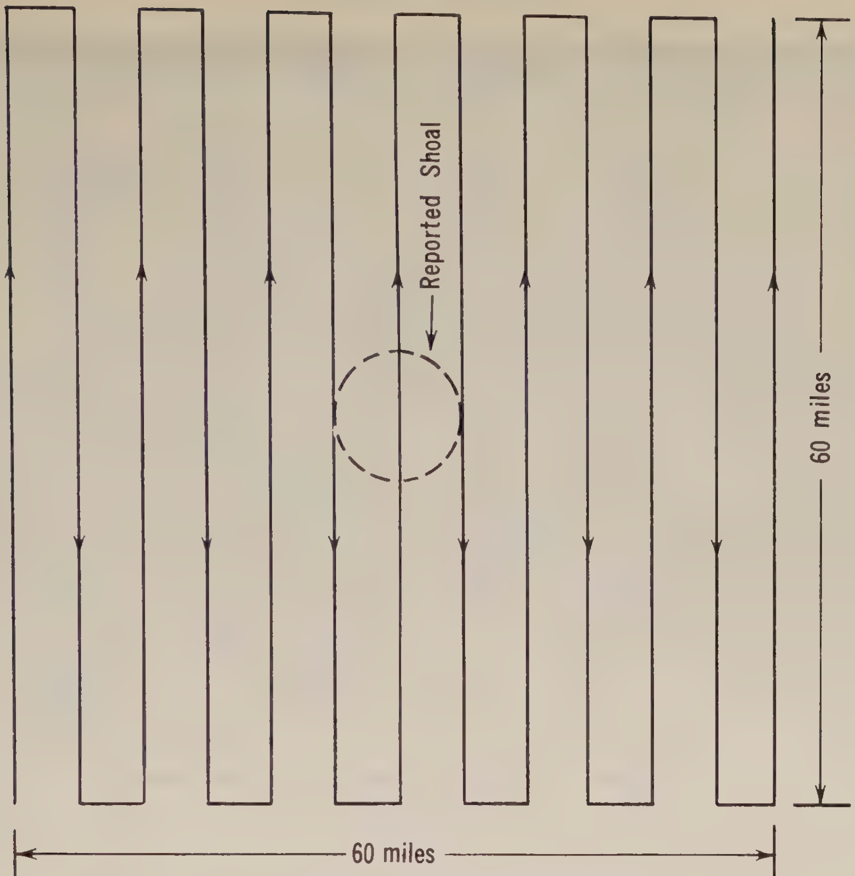

FIGURE 4205b.—Parallel course line pattern.

During such an investigation, by either method, the best control of position can usually be obtained by anchoring a buoy, if practicable, at the center of the area. In some instances, several buoys might be used. Any rig having buoyancy adequate to support the necessary length of anchor cable is satisfactory. The type generally used consists of a steel drum or mooring buoy with a weight attached to a cable, in the case of a large buoy, or piano wire if the buoy is small and of insufficient buoyancy to support a cable. A chain is not generally used. Buoys of this type have been successfully anchored in depths to 2,500 fathoms. The position of the buoy is determined as accurately as practicable, using celestial navigation, loran, or whatever means are available. Position of the vessel is determined relative to the buoy or buoys, using visual or radar bearings and ranges at intervals of half an hour or less. Beyond this range, the best available means are used. A balloon with a suspended radar reflector might be attached to the buoy to extend its range of usefulness. The securing line of the balloon should be at least 400 feet long, if practicable.

Sonar ranging, if available, should be used to assist in the location of shoal areas.

4206. Records.—While a reliable trace of the bottom is being obtained, the recorder should be operated continuously. Each hour, preferably on the hour, the time should be written on the graph, with an arrow pointing to the correct position on the trace. A fix marker may be used if the recorder is provided with one. In addition, the time of sharp changes in depth and other interesting features should be recorded. The date should be entered each watch, and the ship's name given at each end of the graph. Other pertinent information should be recorded. Figure 4206a illustrates a properly marked

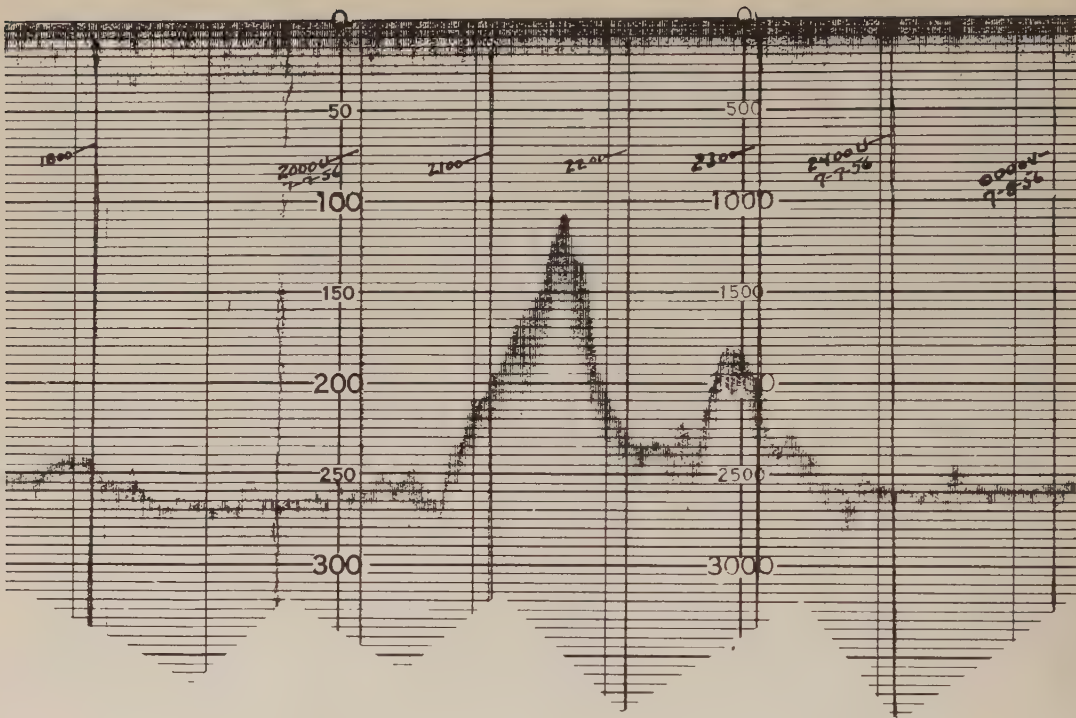

FIGURE 4206a.—A properly marked depth recorder graph.

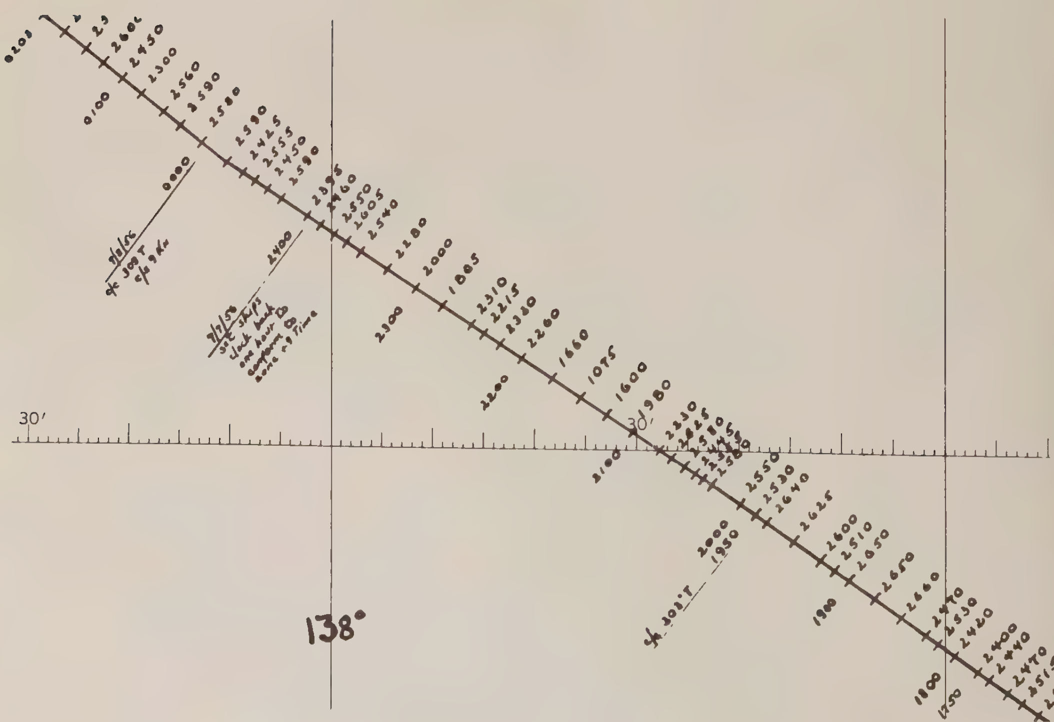

FIGURE 4206b.—An adjusted plot with soundings.

graph. When a reliable trace is not recorded, visible or audible soundings should be recorded in a log at least every five minutes. The time and date of the entries should be included in the log.

A plot of the track should be made on a plotting sheet. On this plot the dead reckoning lines and times should be adjusted to provide a continuous run, without gaps. Pertinent navigational data should be included, but no extraneous information should be given. Soundings should be spaced about one-quarter inch apart on the plot. The position of each sounding should be indicated by a tick with the sounding in fathoms given alongside, at an angle to the track line. Most plotting sheets have printed labels for the parallels of latitude. It is necessary that labels for the meridians be recorded. an item that should not be overlooked. The date of the soundings and the name of the vessel should also be recorded. Accuracy is essential, and neatness is desirable. Figure 4206b illustrates a typical adjusted plot.

When the work has been completed, all necessary information should be sent to the appropriate charting agency, usually the U. S. Navy Hydrographic Office. This should include the unadjusted plot used for navigation, the adjusted plot; data for each fix, with the navigator's evaluation of its reliability, and appropriate comments on weather conditions, etc.; depth recorder trace; and sounding log (if kept). The commanding officer's or captain's forwarding letter should indicate where the soundings were taken, type of sounding equipment, any difficulties encountered, and pertinent remarks regarding estimated reliability of the data. Additional information of value to cooperating observers is given in H.O. Pub. No. 606–b.

CHAPTER XLIII

PHOTOGRAMMETRY

4301. Introduction.—One of the most significant contributions to modern map making has been the development of the precision aerial camera and the techniques for interpreting and utilizing the information appearing on the photographs made by it. Such photographs constitute a detailed and permanent record of all unobscured natural and man-made features of a given section of the earth's surface, and as such, furnish more completely than any other means the information required for making maps. However, all photographs, whether aerial or terrestrial, are perspective views, and it is necessary to change these to orthographic views in order to obtain reliable map information. Although an aerial photograph is often map-like in appearance, there are many errors, both systematic and random, which prevent the photograph from being a true map. The science of photogrammetry is used to eliminate or correct these errors and also to properly record all the photographed information into a true map presentation. Its development into a complex and exact science has made photogrammetry the most efficient, accurate, and economical method for mapping large areas.

It is not the purpose of this chapter to present the detailed theory or working procedure of photogrammetric instruments and methods, but rather to acquaint the reader with the fact that such methods and instruments do exist and also to present simple formulas and techniques that a nonphotogrammetrist can utilize to obtain valuable, map-like information from aerial and ground (or shipboard) photographs.

4302. General photography classifications.—Photography used in map making is of three general classifications:

Vertical (aerial) photography, made with the optical axis of the camera vertical to the earth, or approximately so.

Oblique (aerial) photography, made with the optical axis of the camera at an angle to the vertical.

Terrestrial (ground) photography, made with the camera's optical axis in a generally horizontal position.

Each of these types of photography has its own particular field of usefulness, but the vertical aerial photograph is the type most widely used for mapping, since it most nearly resembles a map.

4303. Vertical photography.—The vertical photograph is not a map, but a perspective projection of three-dimensional terrain onto a two-dimensional photograph. This results in the photographic images being displaced from their true horizontal relationships due to the relief of the terrain features and any tilt of the aerial camera. This in turn results in a photograph which does not have a uniform scale. These displacements of image positions prevent the accurate determination of either distance or direction directly from the photograph. Figure 4303a illustrates the principle of image displacements due to the relief of terrain features.

For regular photogrammetric mapping purposes, vertical aerial photography is accomplished with less than 3° of tilt and in such a manner that there is approximately 60 percent overlap between photographs in line-of-flight, and approximately 20 percent sidelap between adjacent strips of photographs. The 60 percent overlap provides at

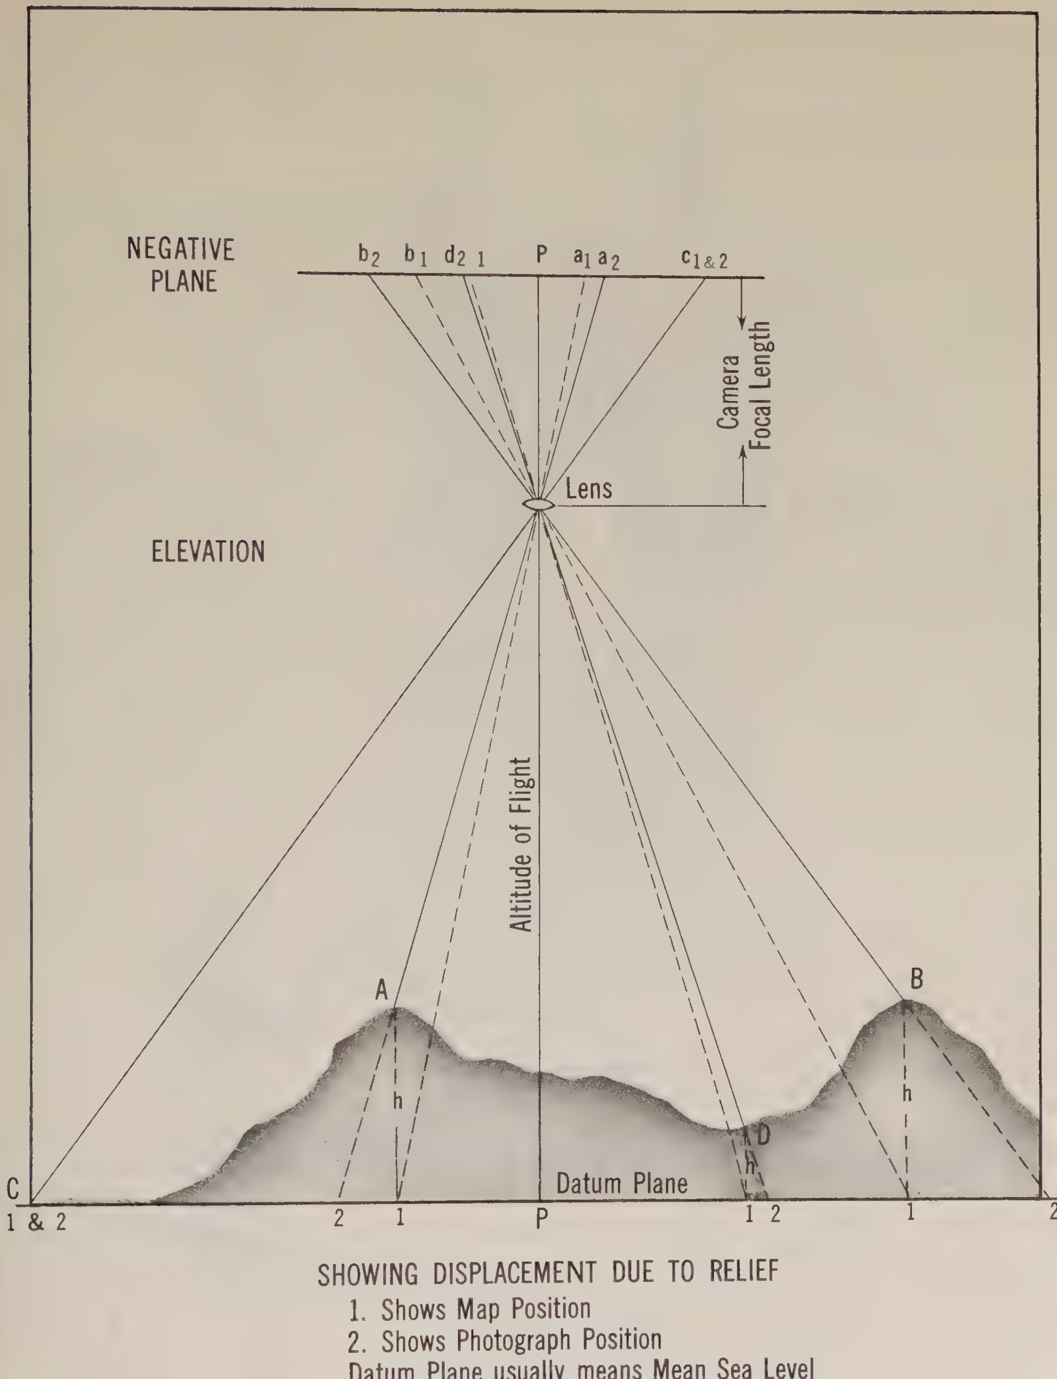

FIGURE 4303a.—Displacement due to relief.

least two different views of all features photographed. This is necessary to achieve the stereoscopic effect by which interpretation and measurements can be accomplished. By understanding and utilizing the geometric properties of this photography, one can obtain the information required to make a map; and accurate vertical, as well as horizontal, measurements can be made.

The **radial line plot** is one method of compiling a **planimetric map** (one showing horizontal position only) from overlapping vertical aerial photographs. Displacement due to relief and small amounts of tilt is corrected graphically by the **radial-line intersection method.** The center of each photograph is located, and any ground control points are identified and marked on the photographs. Auxiliary control points are selected on all photographs to strengthen the network. Radial-line intersections are taken from successive photograph centers to all control points. These intersections define the distances and directions of the points on the photographs.

The ground control points are plotted on a grid or map projection for the purpose of orienting the photographs. The intersecting of the radial lines and the orienting of the photographs to the plotted control network can be done graphically or mechanically through the use of arms or templates. After all the auxiliary control points have been correctly plotted on the manuscript, planimetric detail can be traced from the photographs by aligning corresponding points on the manuscript and photographs.

There are photogrammetric instruments capable of utilizing the basic photographic information to plot a standard topographic **map manuscript.** These instruments encompass a tremendous range from relatively simple monocular devices to highly complex optical and mechanical instruments. In basic theory, they recreate the three-dimensional view as photographed from aircraft, and permit the plotting of these terrain features onto a map manuscript.

Figure 4303b shows the working principle of one of these instruments, the multiplex. Nine-inch square aerial negatives are reduced by the use of a reduction printer to small transparencies called **diapositives.** These are placed in projectors held by brackets above a flat table. The brackets have adjustments by which the relationship that existed between the pictures at the time of exposure can be reestablished to scale with the two projectors. As many as 24 projectors can be placed on a frame. Thus, control established at a known point on the earth can be extended many miles.

The projectors are oriented in such a way that corresponding rays from the adjacent diapositives intersect at the image space above the table. By this means a stereoscopic model of the terrain appearing on the original negatives is precisely created. The adjacent diapositives are projected in complementary colors (red and green) onto a **tracing table** at any level of the stereoscopic model as a two-color **anaglyph,** and the operator views this model through spectacles in which one glass is red and the other green. Briefly, the tracing table consists of a round white disk called a **platen,** in the center of which is a very small illuminated hole. The platen is supported by two columns, and by means of a knurled screw it can be raised and lowered. In this way, the point of light can be made to appear on the surface of the ground, and differences in elevations can be read on a counter mounted on one of the columns. A pencil holder is mounted directly beneath the illuminated point, and the whole device is mounted on agate foot pads so that it can be easily moved over a piece of suitable drawing material. In this way, the operator can trace the horizontal position of selected data, including relief features, in an orthographic presentation of the earth's surface corresponding to the photographic coverage.

4304. Scale of vertical photograph.—The scale of the vertical aerial photograph, usually expressed as a representative fraction (e.g. 1:40,000), denotes only the average

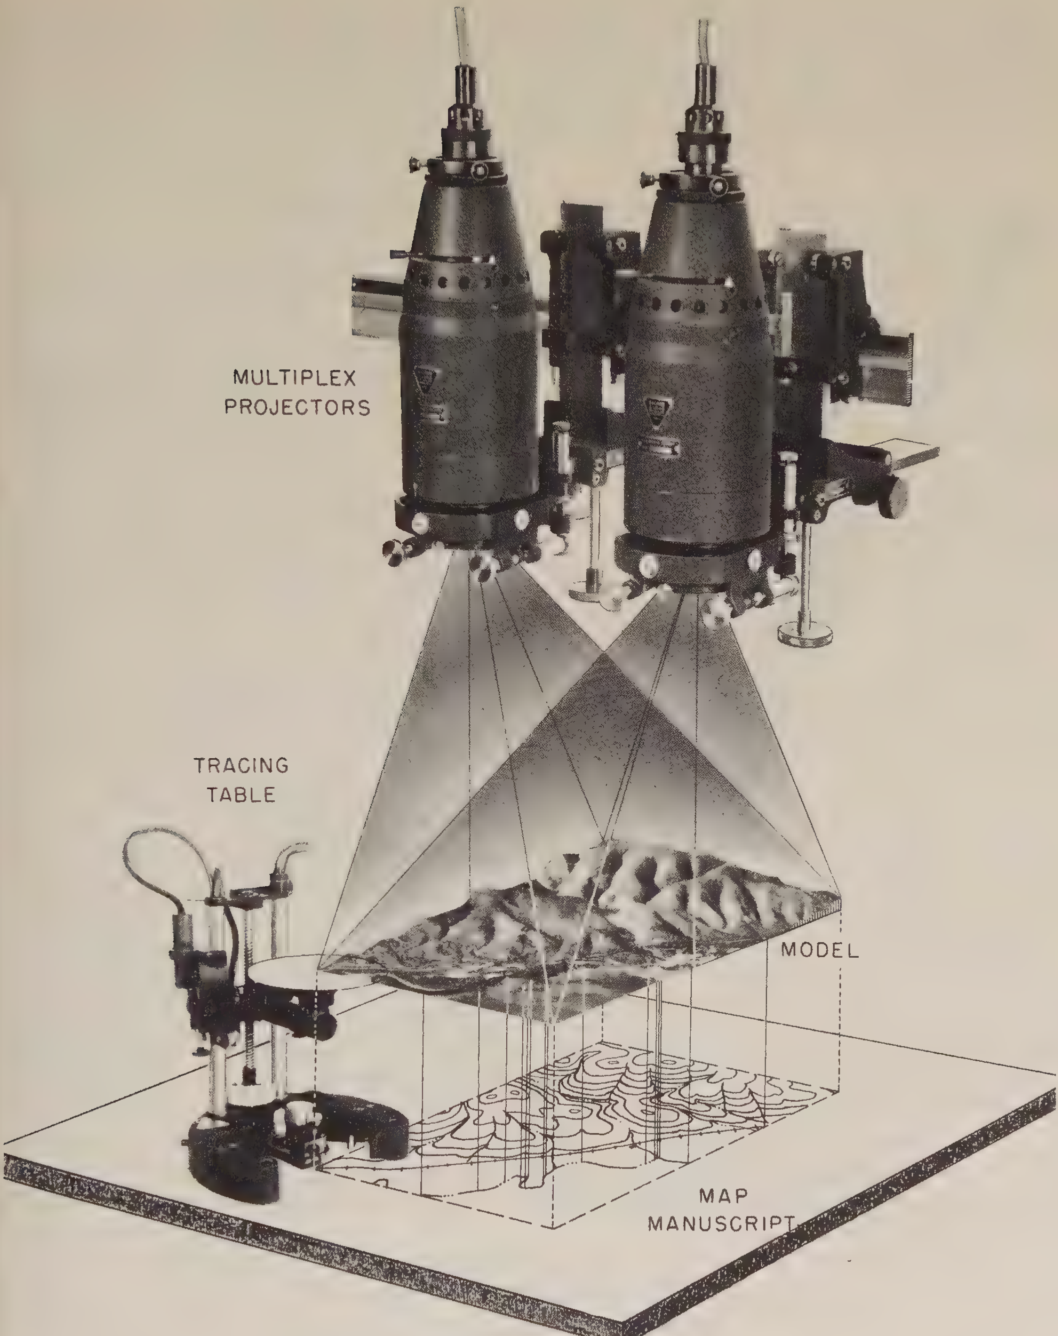

FIGURE 4303b.—Principles of the multiplex.

or approximate scale, for even on an untilted vertical photograph there can be no uniform scale due to the varying elevations to the terrain. If the scale of an aerial photograph is to be determined, two items of basic information must be known: (1) the focal length of the aerial camera, and (2) the flight altitude of the photographic aircraft above the terrain. The scale is determined by the ratio of these factors. For example: If the focal length (f)=6 inches=0.5 feet, and the flight altitude (H)=20,000 feet, then:

$$\text{photo scale}=\frac{f}{H}=\frac{0.5}{20{,}000}=\frac{1}{40{,}000}=1:40{,}000.$$

The approximate scale of the vertical aerial photograph can also be established by comparison of distances on the photograph with corresponding distances on a map of known scale.

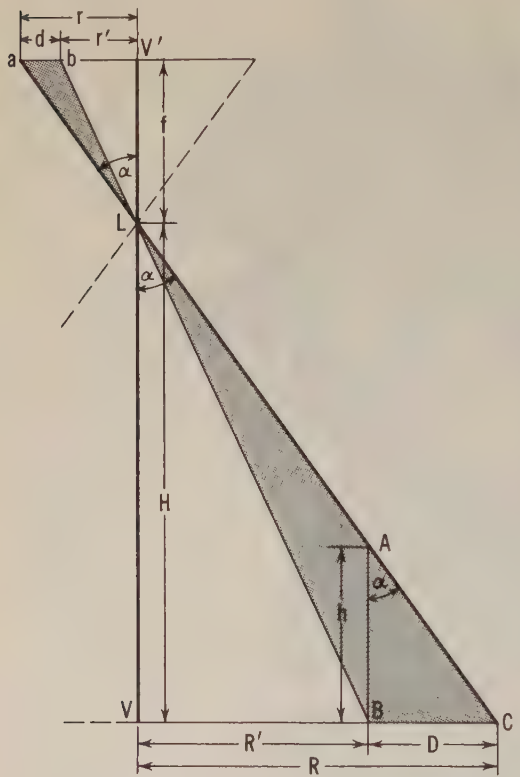

Figure 4305.—Determination of height by image displacement.

4305. Height determination.—If the foreshortened side of an object of considerable height, such as a tower or lighthouse, appears on a vertical aerial photograph, a simple application of the geometric properties of a photograph can determine the true height. The factors which must be known are: (1) the flight altitude of the aircraft above the terrain, (2) the length of the foreshortened side of the object on the photograph, and (3) the distance between the top of the object as it appears on the photograph and the center of the photograph. Refer to figure 4305 for the development of the height-determination formula. In the figure, H is the flight altitude above terrain, h is the height of the object, r is the distance from the top of the object image to photograph center, d is the length of the foreshortened image of the object, and f is the focal length of the aerial camera.

By the geometry of the figure:

(1) triangles LVC, ABC, and $LV'a$ are similar, with angles α equal.

(2) triangles LBC and Lba are similar.

(A) From (1):

$$\tan \alpha=\frac{R}{H}=\frac{D}{h}=\frac{r}{f}, \text{ or } D=\frac{rh}{f}.$$

(B) From (1) and (2):

$$\frac{D}{d}=\frac{H}{f}, \text{ or } D=\frac{dH}{f}.$$

From (A) and (B):

$$D=\frac{rh}{f}=\frac{dH}{f}.$$

Therefore: rh=dH

and

$$h=\frac{dH}{r}.$$

Thus, if the foreshortened image of a lighthouse appearing on a vertical aerial photograph (d) is measured as 0.08 inch, the distance on the photograph from the lighthouse top to the center of the photograph (r) is measured as 3.75 inches, and the flight altitude above terrain (H) is 3,750 feet, the height of the lighthouse is $h=\frac{dH}{r}=0.08\times\frac{3750}{3.75}=80$ feet.

4306. Oblique photography.—Oblique aerial photographs are obtained by tilting the optical axis of the camera from the vertical. The oblique camera has the advantage of being able to photograph vast areas in a single exposure. Oblique mapping photographs are of two types: the **high oblique,** which shows the horizon line; and the **low oblique,** which does not show the horizon. Sometimes two high obliques are exposed in opposite directions simultaneously with a vertical, in order to provide photographic coverage from horizon to horizon, perpendicular to the line of flight. Although this method (named **trimetrogon** after the three metrogon lenses used in the camera system) of employing two obliques and one vertical photograph enables relatively rapid map compilation of large areas, the type of information obtained from obliques is adequate for only small-scale maps of a reconnaissance nature. The use of high oblique photos for mapping is more limited than that of verticals because the methods entailed are more time consuming and the results obtained are ordinarily less accurate. This is due to the perspective distortion of the oblique, and the masking of distant features by closer ones.

Twin low-oblique photography is obtained with a twin-camera arrangement consisting of a pair of wide-angle precision aerial cameras coupled rigidly together. The optical axes of the two cameras lie in a common vertical plane and form an angle of 20° with a plumb line (assuming no tilt) and 40° with each other.

4307. Maps from oblique photography.—High oblique photographs can be used for reconnaissance mapping, particularly in areas where the relief of the terrain is slight and the required map is essentially planimetric. Methods and instruments for use by trained personnel are available for extracting elevations from high obliques, but the procedure is involved, and will not be covered here. Transfer of planimetric detail from the oblique photograph to a map manuscript may be simply and effectively accomplished by a graphical process known as the **perspective grid method.** In basic principle, this method permits sketching of the linear detail (shore line, lakes, rivers, town lines, etc.) from a perspective grid at the picture plane to a rectangular grid at the map plane. For the reconnaissance study of unmapped flat areas, it is feasible for a nonphotogrammetrist to prepare his own base maps by this method, even using pictures taken by himself. It is required only that a distinct and regular horizon line should be visible on the photograph, and that certain basic factors be known, as explained in articles 4308 and 4309.

4308. Construction of the perspective grid.—The perspective grid is drawn on a transparent medium which is positioned securely over the photograph. In the construction of the perspective grid, three factors are required:

1. The altitude of the photographic aircraft.
2. The focal length of the camera lens.
3. The true, as distinguished from the apparent, depression angle of the photograph. This factor can be computed from measurements, as explained in step (7) below.

The first consideration in construction of the perspective grid is the scale to use for the drawing; that is, the size the squares of the map grid are to be, and what distance on the ground each side of the square will represent. Suppose that the perspective

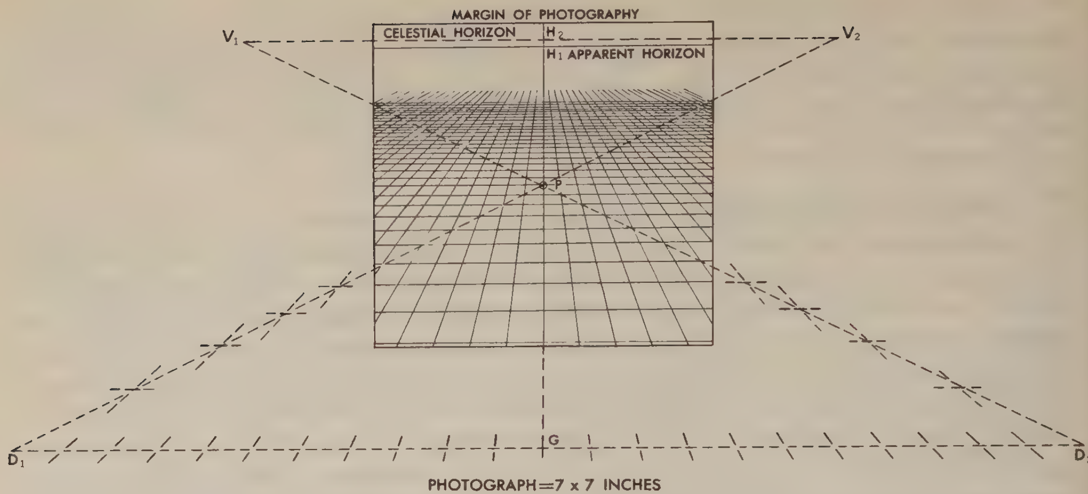

FIGURE 4308.—Construction of a perspective grid for a high oblique aerial photograph.

grid shown in figure 4308 is to be drawn, and it is decided that the map grids are to be one inch square, and that each side of the square will represent 660 feet on the ground. Suppose, further, that H, the flight altitude, was 5,000 feet; that f, the focal length of the camera lens, is 5.216 inches; and that the photograph is seven inches by seven inches. The grid construction follows (shown to reduced scale in fig. 4308):

(1) *On the photograph,* draw a line along the apparent horizon.

(2) *On the photograph,* draw a line perpendicular to the apparent horizon and through the **principal point** (the center or point of intersection of the two diagonals, designated P), extending this line from one edge of the photograph to the opposite edge.

These two lines are the only ones to be drawn on the photograph.

(3) Lay the material to be used for the perspective grid over the photograph, and on it trace the two lines drawn on the photograph (steps (1) and (2)).

(4) Measure the distance PH_1. Suppose this is three inches.

(5) Compute the apparent depression angle by the formula: tangent of the apparent depression angle$=\frac{PH_1}{\text{f}}=\frac{3}{5.216}=0.57515$. The angle having this tangent is 29°54′.3, which is the angle of apparent depression.

(6) Compute the dip (D) by: D in seconds$=58.82\sqrt{\text{H in feet}}$. In the example, $58.82\sqrt{5{,}000}=4{,}159$ seconds, or 1°09′.3. (In the *Nautical Almanac,* dip is now determined by using 58.2 for the constant 58.82. The value 58.8 was formerly used for almanac dip tables. In this example, the use of 58.2 gives a dip of 1°08′.6. With either value of D the answer to step (8) is the same.

(7) Add the dip to the apparent depression angle, to obtain θ, the true depression angle: 29°54′.3+1°09′.3=31°03′.6.

(8) Compute the distance from the principal point to the celestial horizon by: $PH_2=\text{f}\tan\theta=5.216\times0.60229=3.14$ inches.

(9) Scale this distance (3.14 inches) from P, along the principal line to H_2, and draw the line $V_1H_2V_2$ through it, parallel to the apparent horizon.

(10) The scale of the map grid has already been decided upon as being one inch= 660 feet. Compute the distance from the celestial horizon to the front ground line at G, where one inch on the front ground line subtends 660 feet on the ground trace of the photograph, by the formula: $H_2G=\frac{\text{H}\sec\theta}{660}=\frac{5{,}000\times1.16737}{660}=8.84$ inches.

(11) Scale this distance (8.84 inches) from H_2, along the principal line to G, and draw D_1GD_2 parallel to $V_1H_2V_2$.

(12) From G, in both directions along D_1GD_2, measure off one-inch divisions, and from these points draw lines through the vanishing point H_2. These are the meridian lines *of the perspective grid* (not geographic meridians).

(13) Determine the vanishing points V_1, V_2 for the diagonals, by the formula: $H_2V_1=H_2V_2=\text{f} \sec \theta=5.216\times1.16737=6.09$ inches.

(14) Determine D_1, D_2, by the formula: $GD_1=GD_2=\frac{H_2V_1}{PH_2}\times PG=\frac{6.09}{3.14}\times 5.70=$ 11.06 inches.

(15) Draw the diagonals V_1D_2 and V_2D_1. These lines will cross at P if the drawing and computations have been carefully done.

(16) Draw a horizontal line through each intersection of a diagonal and a meridian line, as shown in figure 4308.

(17) Lay out the limits of the photograph, and ink all lines within the photograph limits except the construction lines.

4309. Use of the perspective grid.—Prepare a grid of one inch squares on a separate sheet of paper large enough to take the entire plottable area covered by the photograph. Superimpose the transparent perspective grid over the photograph in its proper position. By inspection, transfer the detail from the photograph to the square grid. This is illustrated in figures 4309a and 4309b. Figure 4309a represents a transparent perspective grid, as if superimposed on a photograph showing a main shore line and offlying islands. Figure 4309b shows the transfer of the shore line and islands from the photograph to the plotting or map grid. The entire area of figure 4309a is not included, to permit a larger scale illustration. The scale of the map grid is one-third the scale of the perspective grid.

4310. Terrestrial (ground) photography is comparable to shipboard photography, and both may be utilized in a similar manner. The principles of the perspective grid method previously described can be adapted for use with terrestrial photography. Another method of determining horizontal positions is to obtain two photographs of the same area taken from different camera stations. The positions of the camera stations must be known and the horizontal directions of the camera axis at the time of each exposure must be determined. The focal length of the camera must also be known. Where the reproduction is not at the same scale as the negative, the reduction or enlargement must be known so that the focal length value may be altered proportionately. Preferably, the celestial horizon should run through the principal point of the photographs and be parallel to the top and bottom margins.

Place a sheet of transparent material over each photograph. Select the points (A, B, C, D, fig. 4310a) for which the positions are desired, making certain that all points are included in both photographs. Through each of these points and also P, the principal point (located by diagonals, as shown), draw a line perpendicular to the horizon. Near the bottom of each photograph draw a line (JK) parallel to the horizon, intersecting all vertical lines at right angles (A', B', C', D', and P'). Extend vertical line PP' (through the principal point), and from P' measure off the focal length, $P'S$, locating the camera station, S. Connect point S with points A', B', C', and D'. Next, place each overlay on the chart with its point S over the correct camera position, and line SP in the direction the camera was facing when the picture was taken. The location of point A on the chart is at the intersection of the two SA' lines, extended if necessary. The other points are located similarly.

If the position of the camera station for any photograph is unknown, it can be determined if there are several correctly positioned points on a chart that are readily

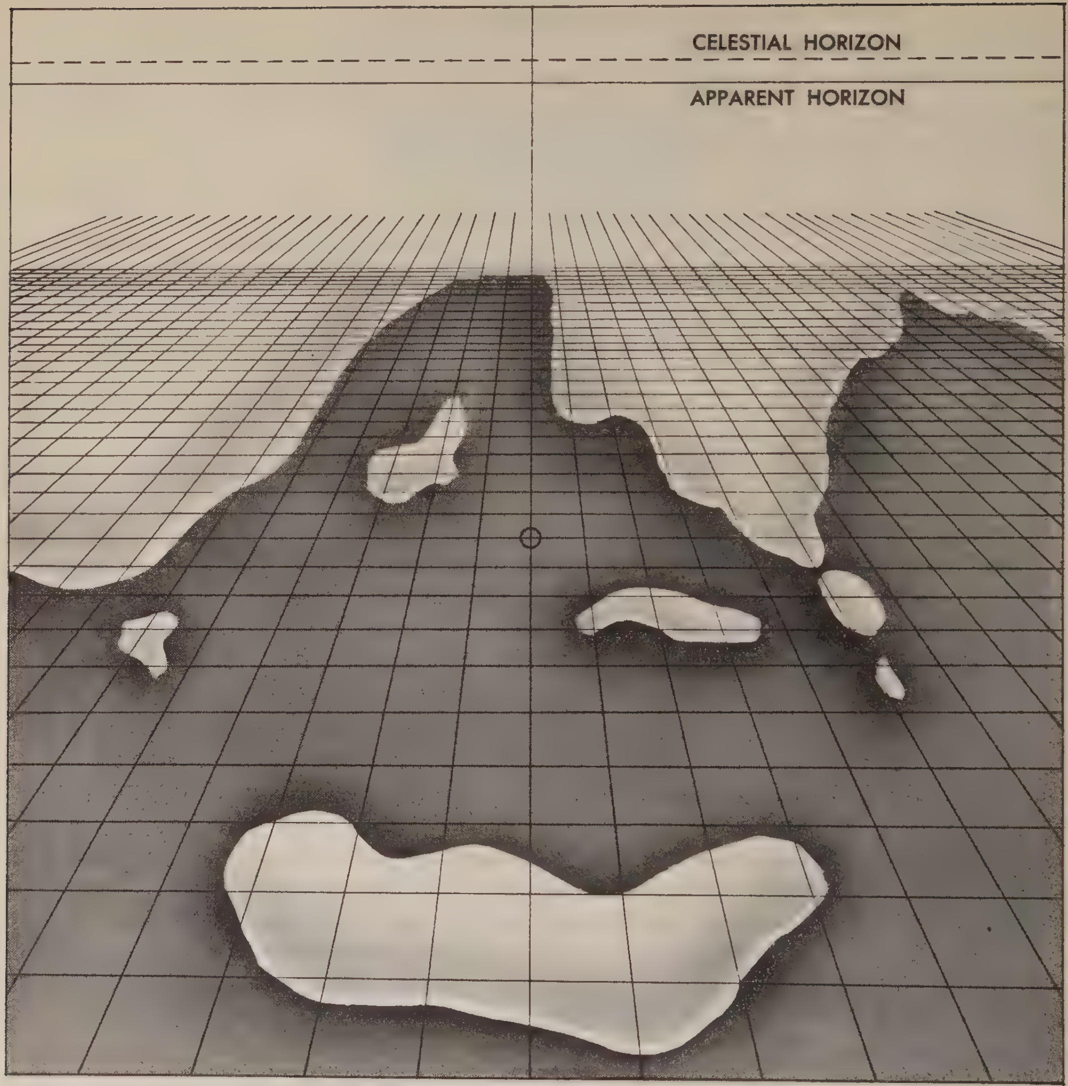

FIGURE 4309a.—Perspective grid as if superimposed upon a photograph.

identifiable on the photograph. The procedure described above is applied to the single photograph, but using the identifiable points (fig. 4310b). The transparent overlay is positioned on the chart so that the radial lines pass through the corresponding points on the chart. The position of the camera station is thus determined by resection (art. 4116).

4311. Photo-interpretation is the examination of photographic images of objects for the purpose of identifying the objects and deducing their significance. In identifying objects from their photographic images, the following characteristics should be considered:

Shape relates to the general form, configuration, or outline of an individual object. The shape of an object appearing on a vertical photograph may differ widely from its shape when viewed from the ground. Because of this, a certain amount of practice and experience is necessary in order to make a reliable identification.

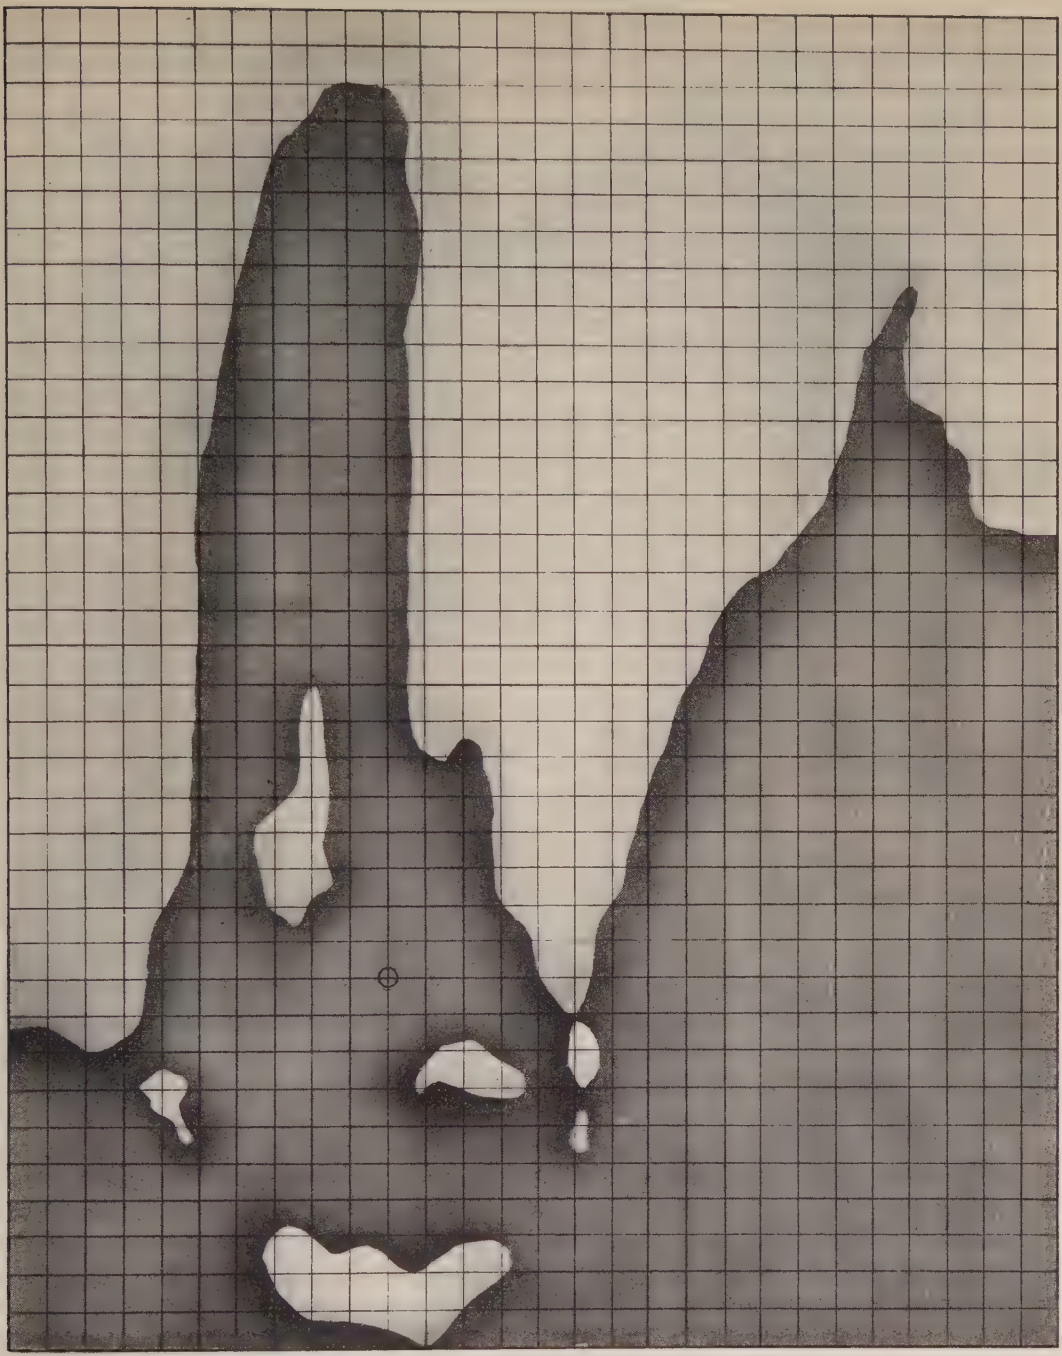

FIGURE 4309b.—Section of a map grid from the perspective grid of figure 4309a.

The *size* of an object as compared with another object can be of invaluable assistance in determining the size of the second object. A truck on a road gives an idea of the width of the road.

Pattern refers to the spatial arrangements of objects. Many objects, both natural and man-made, conform to certain repetitious patterns. For example, streams which

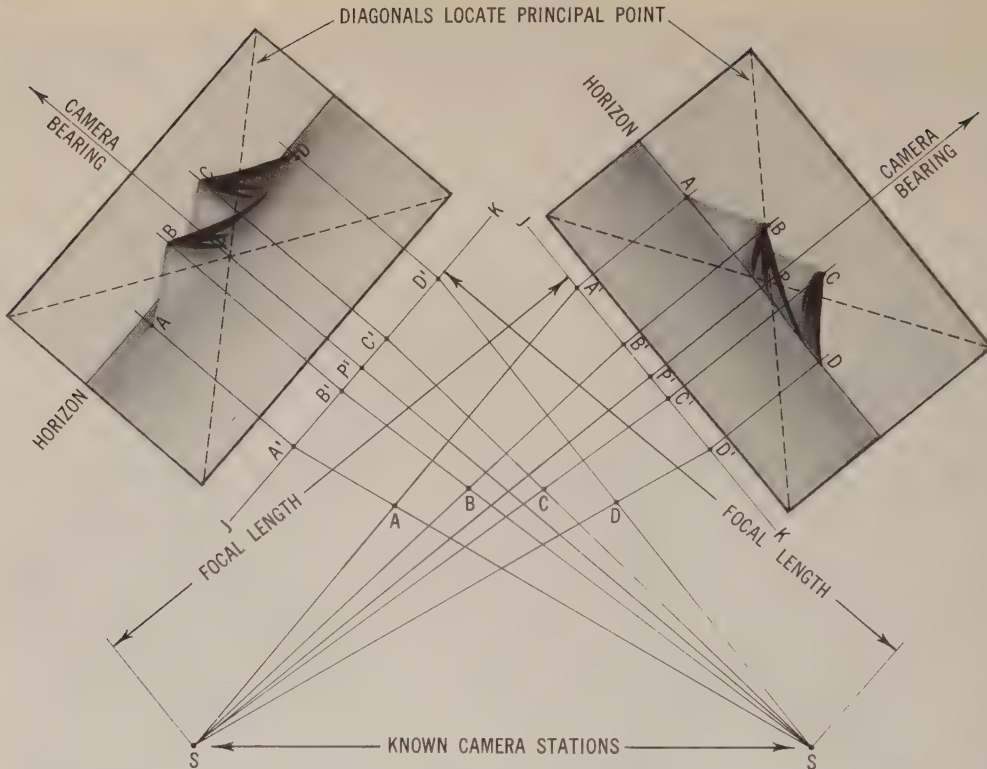

FIGURE 4310a.—Determination of horizontal positions from two photographs.

branch and reunite in a braided pattern are readily distinguished from simple meandering streams.

Tone refers to the shade of gray in which an object appears on a photograph. The tone of an object may differ on two adjacent photographs because the light is reflected back at different angles in different amounts. The image of smooth water may appear light on one photograph and dark on the next. Most roads are good reflectors of light over a wide angle and almost invariably appear as light lines on the photograph.

Texture is the nature of the surface photographed, with particular reference to size and arrangement of individual units. For example, the photographic texture of the beach area on which an amphibious landing is contemplated may indicate the coarseness of particles composing the beach and, thereby, the ability of the beach to support military vehicles.

Shadows frequently give the best indication of the profile view of an object, thus facilitating the identification of the object. Shadows will give an indication as to heights of trees and buildings, types of bridges and towers, and depth of cuts, quarries, etc. Frequently, it is possible to obtain some idea of the character of the relief from the shadows on a single photograph.

Site is the location of an object in relation to its surroundings. It is important in the interpretation of both man-made and natural features. Many types of vegetation are confined to specific topographic sites such as swamps, stream banks, sandy flats, or rock knolls.

CHAPTER XLIV

PRODUCTION OF NAUTICAL CHARTS

The Production of Charts

4401. Introduction.—The nautical chart has become so reliable and readily available that one unacquainted with the tremendous amount of material, labor, and time involved in its production might easily fail to appreciate the contribution made by charting agencies. So dependent has the mariner become upon this commonplace but important aid, that he generally considers it essential to safe navigation.

The four preceding chapters describe briefly the collection of survey data. This chapter sets forth the basic techniques used in the production of nautical charts from survey data and other source material. The information is given so that the mariner might have a better understanding of his chart and its limitations. Thus equipped, he is capable of more effective, reliable navigation. Further, the mariner is an important source of data used in the production and correction of nautical charts. If he is familiar with the use made of these data, he can better evaluate the information which comes to his attention, and can forward it in form that will be of value to the charting agencies. With such information, these agencies can produce more accurate charts of greater usefulness to the mariner.

4402. Federal charting agencies.—The U. S. Navy Hydrographic Office has responsibility for producing and maintaining nautical charts of any area of interest to the United States Navy or merchant marine which is not the responsibility of other U. S. charting agencies. The U. S. Coast and Geodetic Survey, of the Department of Commerce, has responsibility for charting the coastal waters of the United States and its territories and possessions. The U. S. Lake Survey, of the U. S. Army Corps of Engineers, has similar responsibilities for the Great Lakes. Consequently, the Hydrographic Office limits its activities to foreign waters and the high seas, except in time of war or national emergency. Under these circumstances, charting activities would be carried out under a coordinated program.

The charting activities of these agencies seek to provide maximum navigational safety and facility to vessels of the United States Navy and merchant marine. They keep informed of new navigational requirements, and utilize the latest developments in the production of charts. Many new methods and instruments originate with these agencies.

While the information given in this chapter relates primarily to the methods, techniques, etc., of the U. S. Navy Hydrographic Office, it applies, with minor variations, to those in use by the U. S. Coast and Geodetic Survey and other charting organizations, both domestic and foreign.

4403. Improvements in charts.—The nautical chart has kept pace with the latest developments in the field of marine transportation and navigation. Special-purpose nautical charts have been produced to satisfy specific navigational requirements, such as those of loran and radar. New or improved developments in electronic positioning systems, magnetic observations, and aerial photographic coastal and topographic delineations are some of the factors instrumental in improved chart accuracy.

Presentation of data is planned to conform with standard specifications which have been established by U. S. Government charting agencies and the International Hydrographic Bureau, located in the Principality of Monaco. This organization, established in 1921, is composed of more than 30 of the leading maritime nations of the world. Its purpose is to promote international agreement in the form of nautical charts and publications, and to effect collaboration in the common task of collecting and disseminating hydrographic information. Adoption of chart standards and the practice of exchanging cartographic information and techniques among various agencies and scientific and professional societies have aided materially in improving the nautical chart. Some of the prominent innovations which have improved the appearance and utility of the nautical chart are the following: use of colors to accentuate navigational hazards, revision and simplification of typography for improved legibility, use of tint shading in combination with contours to give a pictorial presentation of relief. The transition in presentation has been gradual, with convenience to the chart user being constantly kept in mind.

4404. Sources of chart data.—The preferred source of data used in the construction of nautical charts is the hydrographic survey (ch. XLI). The completed survey usually covers more extensive areas than the charts because of chart size limitations and the absence of chart requirements in areas without special naval or economic significance. However, hydrographic survey plans generally include a proposed chart layout to insure sufficient detail at suitable scale in potential chart areas.

In addition to surveys, chart data are collected from many other sources. Foreign data, the main source for U. S. Navy Hydrographic Office nautical charts, are collected in published chart form on a continuing basis under exchange agreements with member states of the International Hydrographic Bureau and with other maritime countries. Various government agencies, engineering firms, educational institutions, and private individual sources furnish documented information which is incorporated into nautical charts. Each week, the Hydrographic Office receives more than 400 documents which are evaluated for use in preparing charts and publications. The published chart does not outwardly reflect the amount of information which is screened during its construction. The following list of source material is representative of the type from which useful information is obtained:

Surveys and charts of the United States and foreign countries (hydrographic data).

Maps (transportation, topography, planimetry, and communications data).

Periodicals, travel folders, atlases, and gazetteers (place names, town plans, and descriptive data).

Photographs (aerial mapping and others).

Mariners' reports of port facilities and other miscellaneous information (harbor and dock construction work, conspicuous aids and dangers to navigation, etc.).

Sketches (used to verify and amplify other information).

Notice to Mariners (navigational data).

4405. Chart production methods.—Four common methods of producing nautical charts are in use at the U. S. Navy Hydrographic Office: construction of the chart from modern U. S. Navy surveys; production of the chart from a compilation mosaic (art. 4416), based upon numerous foreign charts; redraft of an existing foreign chart; and facsimile reproduction of an existing foreign chart. The last method is employed only in emergencies, and the facsimile is not sold to the public. A fifth method of increasing popularity is the modified facsimile reproduction of foreign charts (based upon bilateral agreement), which are sold as H.O. charts.

Copper engraving of nautical charts is no longer carried on by the U. S. Navy

Hydrographic Office, having been replaced by methods considered more economical. Plastic engraving (engraving on plastic) of the chart original, recently introduced, is a promising source of further reduction in time and cost.

Photolithography is the principal chart reproduction method used. Negatives are made on glass, film, or plastic, with reproduction plates of zinc or aluminum.

4406. Chart terminology.—The following terminology is in use at the U. S. Navy Hydrographic Office:

New chart. A chart published for the first time, covering an area not previously charted at the same scale by the same organization.

New edition. A chart incorporating corrections too numerous or extensive to be reported in *Notice to Mariners.* A new edition makes previous printings obsolete.

Corrected (New) print. A chart incorporating corrections which have been published in *Notice to Mariners,* and other information of insufficient importance to justify a new edition. Chart dates are discussed in article 506.

Reprint. A chart reprinted without any corrections or changes.

Field chart. A chart published on board a survey vessel, and reprinted by the Hydrographic Office. It is identified by the letter "F" preceding the chart number.

Chartlet. A graphic supplement to *Notice to Mariners* of corrections which are too extensive for the narrative version.

Proof. A copy of a chart made prior to release for final processing. **Photo proofs** are made from negatives. **Litho proofs** are made from the printing plates, in any desired color. A **composite proof** is a combined proof of more than one color plate. A **watercote** is a composite proof, in color, from negatives.

Withdrawal. A chart removed temporarily from issue with the intention of replacement or reissue at a future date. All copies are destroyed, except standards for record purposes. The printing plates may either be retained or destroyed.

Cancellation. A chart permanently removed from issue. All copies and printing plates are destroyed, except standard copies for historical purposes.

Discontinuance. Removal from issue of a reproduction of a foreign chart.

Elements of Chart Construction

4407. Drafting instruments.—The ordinary drafting instruments are employed in making charts. In addition, the following have proved useful in compilation and drafting of a nautical chart:

Pantograph (fig. 4407a), a parallelogram-linkage device for reproducing a drawing at a different scale. A **pantograver,** a pantograph which corrects for distortion due to unequal expansion or contraction of the paper of the source material, is used by the U. S. Navy Hydrographic Office to make corrections on wet (glass) plates.

Projection-ruling machine (fig. 4407b), a device for drawing the meridians and parallels of a map projection.

Vertical projector (fig. 4407c), a device for projecting a vertical aerial photograph (arts. 4302–4305), drawing, or other chart onto a work table at any scale between specified limits, so that details can be traced onto a map manuscript (art. 4303). The projector shown is portable, stands 74 inches high when the movable carriage is at the top of its travel, and provides for any scale from ⅓ to 3½ times the original.

Light table, a table with a glass top over a light source, to facilitate inspection by direct comparison of different charts of the same scale, and the tracing of a drawing at the same scale. Light tables are available in a variety of sizes and shapes. They may be part of another device, as shown in figure 4407b, or separate. A portable version requiring a table or desk for support is called a **light box.**

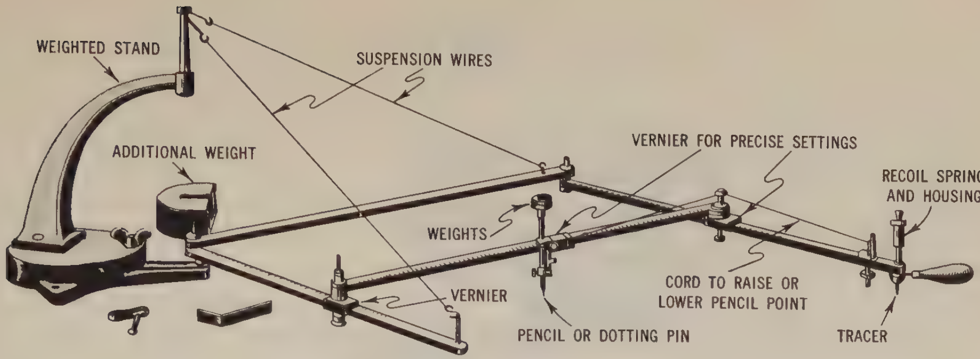

FIGURE 4407a.—A suspended pantograph.

Three-arm protractor (fig. 4011c), a device for plotting a position from horizontal sextant angles.

Proportional dividers (fig. 4011d), a device for transferring distances at a different scale.

Spacing dividers (fig. 4011e), a device for dividing a length into equal segments.

Beam compasses (fig. 4011b), a device for drawing circles of large radius, or measuring distances too great for ordinary compasses or dividers.

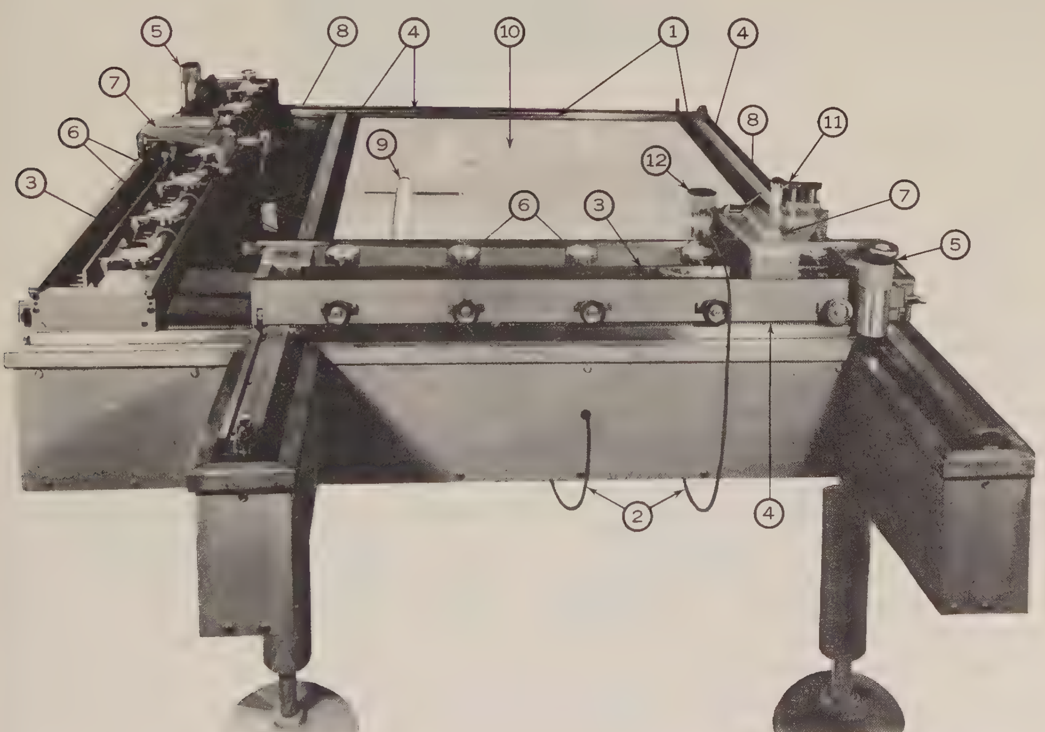

FIGURE 4407b.—Projection-ruling machine. 1. Metric bar scale(s), subdivisions in millimeters. 2. Power supply to illuminate light table and microscopes for reading metric bar scales. 3. Metal spline—can be set to rule straight or curved lines. 4. Gear tracks for carriage(s) to travel on. 5. Microscope for reading metric bar scales. 6. Dials for setting curvature in metal spline. 7. Ruling pen carriage. 8. Ruling pen. 9. Fluorescent light. 10. Transparent glass table top (light table). 11. Rectangular (X−Y) coordinate plotting device. 12. Microscope for reading scale on movable plate.

FIGURE 4407c.—Portable vertical projector.

Road pen (fig. 4407d), a device with a double pen, to permit drawing of two curved lines with constant distance between them.

Plastic splines, long narrow strips of plastic material, which can be bent into a large variety of curves, to form a pen guide for drawing curved lines.

Border-scale subdividing device (fig. 4407e), a mechanical device for drawing equal subdivisions of a border (latitude and longitude) or similar scale. The illustration shows: *A*, a steel straightedge 60 inches long which is secured, by weights or clamps, parallel to the inside border or neat line of the chart; *B*, steel divider plate, one of 12 plates measuring $9 \times 4 \times \frac{1}{16}$ inches and cut with deep, diverging grooves; *C*, steel triangle to be placed with its base against the divider plate; *D*, clamp screws for securing the divider plate to the straightedge; *E*, knob for controlling a screw to move the divider point toward or away from the straightedge; *F*, divider point, which rests in the grooves of the divider plate; and *G*, a set screw to prevent creeping of the divider point. When the device is set up, the divider point is set so that the distance between consecutive grooves is the required distance between graduations of the scale. For a variable scale such as that for latitude on a Mercator chart, this setting must be changed periodically for accurate results.

Diagonal metric scale (fig. 4011a), a device for measuring distances in metric scale units.

4408. Drawing material.—The drawings for a nautical chart should be made on a dimensionally stable drafting medium for maximum accuracy. Plastics, "Duco" plate, and metal-laminated paper, all have minimum distortion qualities and good inking surfaces. The vinyl resins, introduced in the United States in 1928, are among the more recent materials receiving widespread use. Plastics, known under many trade names, are produced in opaque, transparent, and translucent sheets. The "Duco" plate is a grained zinc lithographic printing plate, sprayed with a good grade of enamel paint, which produces a good drafting surface. Metal-laminated paper is produced by mounting a good grade of drawing paper (Bristol board) on a metal plate, using an adhesive and pressure. The metal plate used is normally a zinc or aluminum lithographic printing plate. Use of this type of drawing medium has lost much of its popularity since the introduction of plastics.

FIGURE 4407d.—Swivel road pen in contour penholder.

4409. Reduction methods.—Source material at the same or larger scale as the compilation manuscript is frequently employed in cartography. This practice avoids inaccuracies which might be introduced in enlarging smaller scale data to the scale of the compilation. The four principal methods of reduction are by camera, projector,

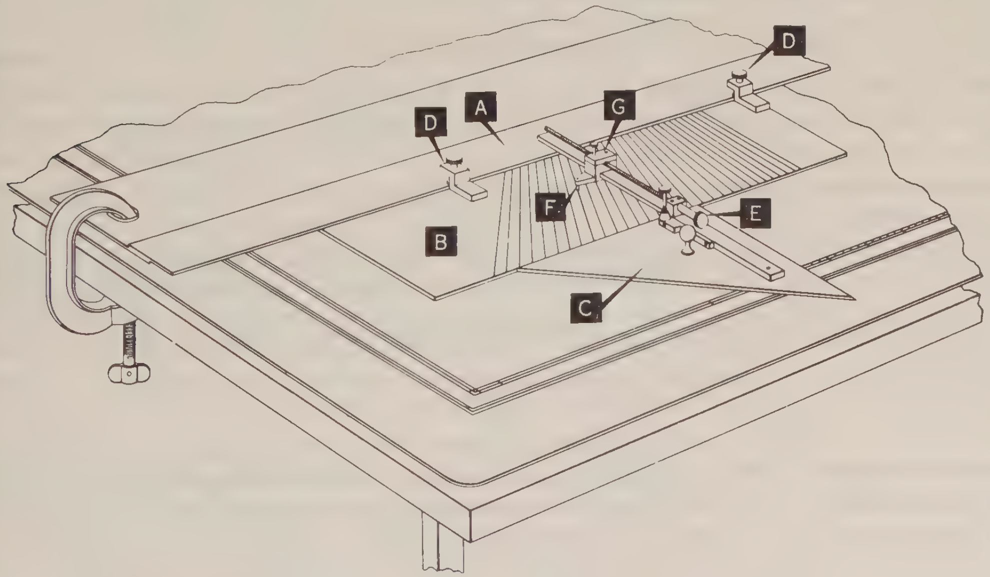

FIGURE 4407e.—Border-scale subdividing device.

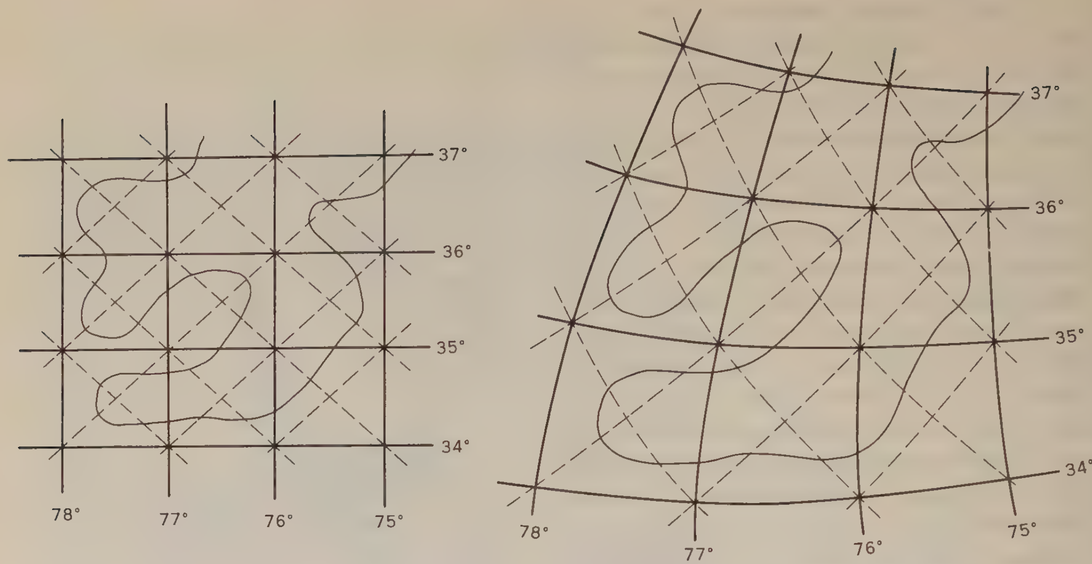

FIGURE 4409.—The "diagonal square" method of sketch plotting.

pantograph, or "diagonal squares." The camera method is the most accurate and is preferred when reduction is the only consideration. In this method the source material is photographed to the desired scale. The projector (fig. 4407c) and pantograph (fig. 4407a) are used when the work is not extensive, and some alterations are to be made. The "diagonal square" method is used to "sketch-plot" data from one scale or projection to another, for example shore line data from a Mercator chart replotted onto a gnomonic or an azimuthal equidistant projection. This method, similar to the perspective grid method of photogrammetry (art. 4309), is illustrated in figure 4409.

4410. Datums.—As explained in chapter XLI, each survey has an "origin," and geographic coordinates of other points are determined with reference to this control point. In some regions, a single origin has been used as control for an extensive area. A system of control points established with reference to a single origin is called a **datum** (plural in this usage is *datums*, not *data*), and given an identifying name. Examples are the North American Datum of 1927, Tokyo Datum, Nahrwan Datum, and the Kelienphur Datum. Since each origin was determined independently, coordinates determined with reference to one datum will not agree with coordinates of the same point determined with reference to a second datum. Normally, there is no confusion because various points are generally defined with reference to a single datum, which is used for the entire area. The limits of a given datum are usually defined by some natural barrier such as an ocean, uninhabited area, etc., so that transitions do not generally occur at a troublesome place. Occasionally, political boundaries of adjacent countries prevent the establishment of geographic coordinate agreement at common stations.

A datum which controls geographic positions of points on the earth is called a **horizontal datum** to distinguish it from a reference level for heights and depths, called a **vertical datum.** For depths, the reference level found to be most realistic for measuring the height of tide is used for charts. This varies in different parts of the world, as indicated in appendix M. This reference level is sometimes referred to as the **chart datum.** In nearly all instances it is some form of *low* water. Heights are nearly always indicated with reference to *mean* sea level or *high* water. Therefore, two different vertical datums are generally used for the same chart.

When the information is available, both horizontal and vertical datums are indicated in the chart legend. If a chart extends over more than one datum, it is normally of such small scale that differences between datums are not of significance.

4411. Borders and scales.—Selection of the border style to use depends primarily upon the scale of the chart, but consistency with other charts in the vicinity is a factor. In general, some form of **plan border** (fig. 4411a) is used for charts of scale larger than 1:50,000; and a **scale border** (fig. 4411a) for charts of smaller scale.

On large-scale charts, **graphic scales** are usually added. On recent charts with plan borders, yard scales are placed along the right and left sides, and both kilometer and nautical mile scales at the top. On charts with scale borders, and older plan border charts, graphic scales are shown at a convenient location inside the border. When this

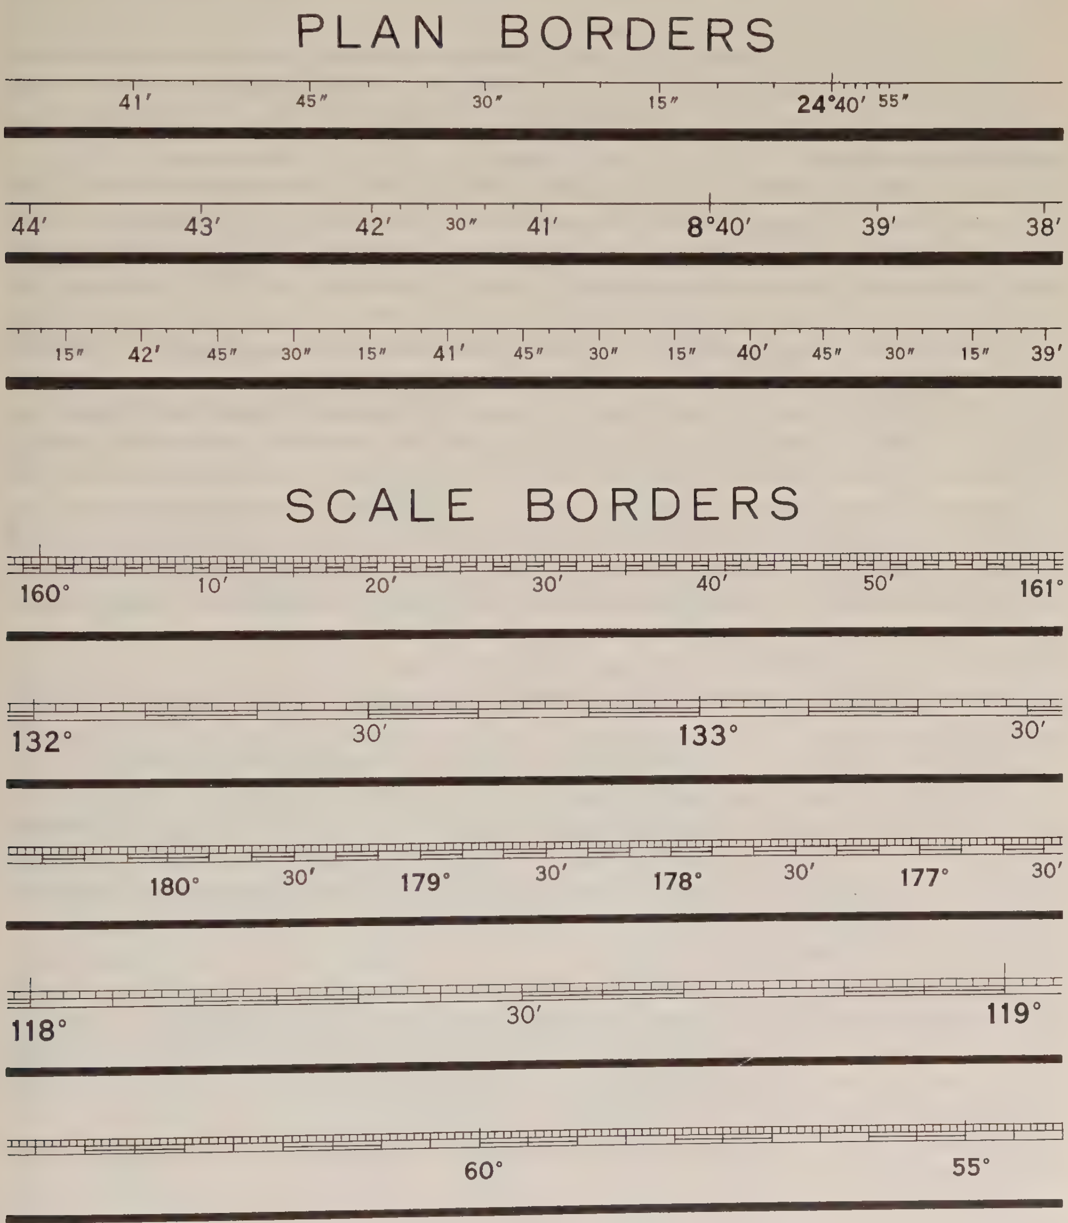

Figure 4411a.—Border styles.

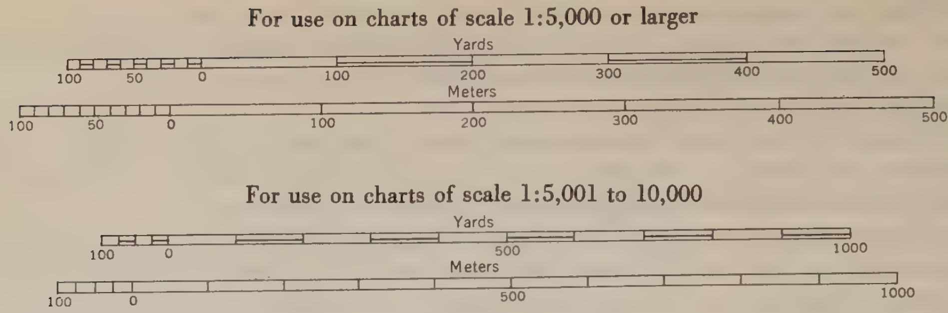

FIGURE 4411b.—Typical graphic scales.

is done, a nautical mile scale is given first, followed by a yard scale and a meter scale. The number of yards and meters shown is dependent upon the amount of space available, the scale of the chart, and the overall size of the chart. Figure 4411b illustrates typical graphic scales.

4412. Charted details.—The standard symbols and abbreviations which have been approved for use on nautical charts published by the United States of America are shown in appendix K. These are in substantial agreement with the recommendations of the International Hydrographic Bureau. From time to time changes in the standards are made to keep pace with changing requirements.

Topographic data are normally obtained from aerial photogrammetric compilations, surveys, and existing maps and charts.

Depths are indicated by soundings or explanatory notes. Only a small percentage of the soundings obtained in a hydrographic survey can be shown on a nautical chart. The least depths are generally selected first, and a pattern built around them to provide a representative indication of bottom relief. In shallow water, soundings may be spaced 0.2 to 0.4 inch apart. The spacing is gradually increased as water deepens, until a spacing of 0.8 to 1.0 inch is reached in deeper waters offshore. Where a sufficient number of soundings are available to permit adequate interpretation, depth curves are drawn in at 1-, 3-, 6-, 10-, 20-, 30-, 50-, and 100-fathom depths. Other features are shown as indicated in chapter V and appendix K.

Aids to navigation are shown by symbol and legend, as indicated in chapter V and appendix K.

Place names are given according to sources and decisions recommended by the United States Board on Geographic Names. The general policy is to use the local source. Foreign names are used in foreign areas. Generally, international features such as the Gulf of Mexico or a river that flows through several countries (for instance, the Danube) are given the commonly accepted English name. The names of countries are also given in English. When appropriate, the English equivalents of foreign terms are shown in a glossary on the chart.

All letters and numbers shown on a chart are printed on sheets of cellulose acetate or white paper, backed with a suitable adhesive which adheres to the drafting material when pressed into place. This practice promotes uniformity and legibility. Various type styles are used to distinguish between different kinds of features and to provide a pleasing appearance.

Notes are used to convey information which does not lend itself to convenient symbolization.

Compass roses are placed where they are readily available for use, yet obscure a minimum of chart information. The number, size, and location are suited to the individual chart.

The chart title is placed at a location that will result in minimum loss of chart information, preferably on land and in one of the corners.

The official seal of the charting agency is generally placed above the chart title.

The chart number is placed at several convenient locations in the margin. When a chart is cancelled, its number is not reassigned to another chart for several years. When a series of charts is planned, a block of numbers is reserved to provide continuity throughout the series.

When a chart is prepared by a government charting agency, and printed by a different government agency or commercial printing establishment; or if a government charting agency prints a chart for another office or department of the government, a suitable imprint note is placed in the bottom margin.

From Requirement to Printed Chart

4413. Requirement.—A new or altered chart comes into being as a result of recognition of a requirement. This requirement may be established by the charting agency itself, from its continual review of existing charts, the receipt of new information, and the needs of operating units; or it may originate with the operating forces or military planners. Whatever its source, the requirement precedes all other steps in the production of the chart.

4414. Estimate of the situation.—Having recognized the requirement, the charting agency having jurisdiction then studies the situation to determine priority and availability of source information. The intended use, required scale, and urgency are considered in selecting the chart production method (art. 4405).

If a survey is needed, the type, extent, and thoroughness are determined according to the availability of survey vessels, personnel, and other pertinent factors. A thorough hydrographic survey is a slow and costly process. If it must be preceded by geodetic control or aerial photographic surveys, the time and expense are increased. Several weeks may be needed to thoroughly survey a single harbor of moderate size. Survey operations are generally planned on a long-range basis to provide adequate coverage for an entire area once operations have begun. In time of war or national emergency, such plans may have to be abandoned and survey ships sent into forward areas. During World War II, survey ships went into the Pacific with the fleet, and it was not uncommon for survey parties to be in operation on shore before fighting had ceased. To meet urgent requirements, the larger survey ships were provided with drafting and printing facilities so that charts could be produced almost as soon as the data were collected. In time of peace such urgency is not generally required.

4415. Research and planning.—Before construction of a chart begins, all available data are investigated and evaluated. All details of the chart are planned, and specifications and procedures are prepared. The best sources of data are recommended. The area is selected to provide maximum usefulness consistent with limitations imposed by scale, size of sheets that can be accommodated by the printing press, land and water configuration, etc. The use expected to be made of the chart is an important consideration. Port and harbor charts normally portray the most important hydrographic region centered on the sheet, while approach charts embrace maximum sea room and only a limited amount of land area, sufficient to include the prominent features of navigational value. Care is exercised to avoid omission of important aids to navigation, river entrances, channels, etc. This often results in some overlapping of adjoining charts. The extent of adequate survey and other compilation data are also considerations.

The chart projection is selected to meet the requirements. Nearly all nautical charts are on the Mercator projection, but the gnomonic, Lambert conformal, and other projections are used for special-purpose charts. This subject is further discussed in chapters III, V, and XXV.

4416. Compilation.—From the recommended sources, the compiler selects the data to be used. The task of determining what to include and what to omit may be of considerable magnitude, particularly when some of the information is inconsistent or of questionable reliability. The skill and wisdom with which this assignment is filled has a direct bearing upon the value of the completed chart.

Various methods of compilation are in use depending upon the amount and nature of the data. When most of it comes from published charts, the compiler may prepare a film positive **compilation mosaic.** To do this he computes and drafts the **graticule** (latitude and longitude lines for the map projection used) and plots the control points at their correct positions. The source material is photographed to the scale of the chart, and film positives are provided. These are secured to the graticule in their proper geographic positions. If necessary, the film positives are cut into small pieces, so that errors in positions of distorted features can be proportionately distributed between control points. Deletions and corrections are then made, and broken lines are connected.

The compilation is carefully reviewed for completeness and accuracy before a contact negative is made. Black-line paper prints are made for specification sheets, and light blue-line plastic prints for drafting. The blue-line prints are made on stable plastic material so that drafting can be done directly on the print. Since light blue does not photograph, only those features inked in black will appear on the negative to be made of each finished drawing for chart reproduction. The black-line prints are used to indicate which items to include on the finished drawing. Generally, separate prints are used for indicating topographic and cultural features, hydrographic features, type faces and sizes, and approved geographic names.

4417. Drafting of the **chart original** is done on a medium having minimum distortion qualities. The graticule and borders are drawn first, followed by planimetric (horizontal) detail, and then relief. Next, the lettering is added. The chart title, notes, etc., are added last, so they will not interfere with charted features.

A separate drawing is made for black and for each color to be shown on the chart. The use of several draftsmen on the same chart permits the work on the various drawings to go forward simultaneously and makes better use of the difference in experience and skill of the various draftsmen. The preparation of the chart originals for a single chart may require several months of continuous drafting.

4418. Review and edit.—When drafting has been completed, the chart original is reviewed by an experienced cartographer. He carefully checks every detail for accuracy, and consults the latest *Notice to Mariners* and all other sources, to be certain that nothing that should be charted has been omitted, and that the latest data have been used. Any corrections to be made are indicated on a transparent overlay which is returned with the chart original to the draftsman for action.

When all corrections have been made and checked, the chart original goes to a chart editor. Here it is checked to see that the line work is sharp and clear, the type is securely fastened, and that all work is in accordance with established standards. Another check is made to be sure that the latest and most complete information has been used.

When the chart editor is satisfied that the chart original meets the foregoing requirements and is safe for navigation, he releases it for reproduction. The various steps in preparing a chart original by the mosaic process are shown in figure 4418.

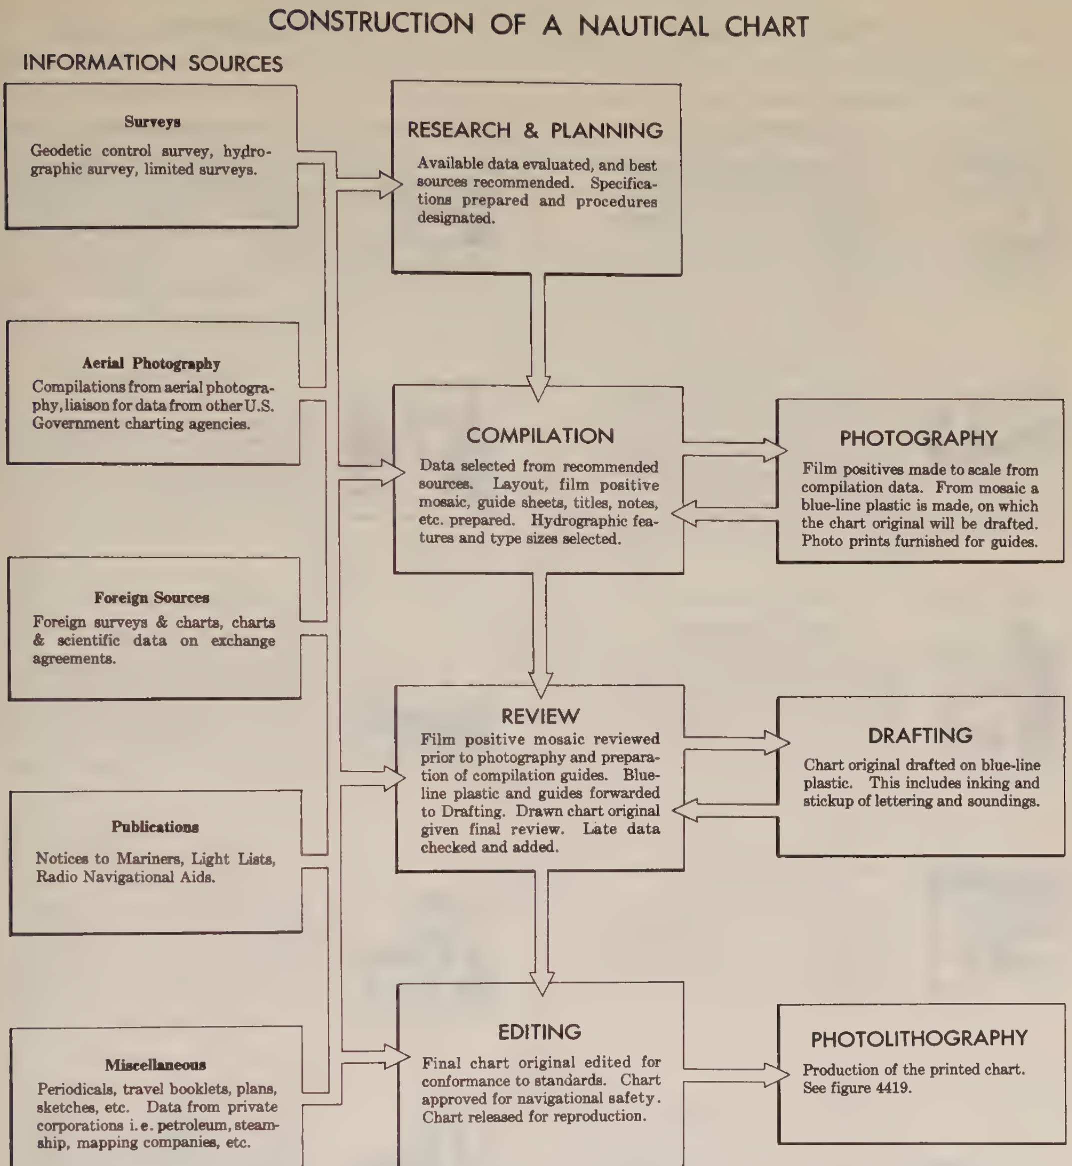

FIGURE 4418.—Flow of work in the construction of a nautical chart by the mosaic method.

4419. Reproduction.—Three basic processes of reproduction (printing) are in use commercially: **letterpress** prints directly from raised type or other image; **gravure** prints directly from a depressed image; and **lithography** prints indirectly (by **offset**) from a surface that is neither raised nor depressed, operating on the principle of the mutual repulsion of grease and water. The lithographic printing plate has a grease image which is receptive to greasy ink, and a nonprinting portion which is receptive to water. Charts are usually reproduced by **photolithography,** which uses photography in the preparation of the lithographic plates. The essential steps in the reproduction of a chart by this process are shown in figure 4419.

In this process, the results of each step are checked carefully. A chart editor edits black photo proofs made from the negatives, and color litho proofs made from the plates. During printing, a continual check is made by the pressman to insure uni-

FIGURE 4419.—Flow of work in the photolithographic processing of a nautical chart.

formity of impressions and accurate "register" (each color being printed at the correct place on the chart). The highest standards possible are maintained throughout the entire operation.

When printing is completed, the plates are removed from the cylinders, cleaned, and the image side given a protective coating of soluble gum arabic and asphaltum. The plates are then stored in vertical racks. The glass negatives have already been stored. A photographic duplicate of the chart original may have been made, and the original and a copy stored at separate locations for possible future use.

4420. Chart record.—A record of each chart is maintained to provide a history, from the authorization of its first edition to the date of the last action, perhaps many editions and printings later. The record accompanies the chart original throughout production, with appropriate entries being made as it progresses through the various steps. Included in the record are such data as sources of information used, method of construction, the map projection graticule computation, geodetic control used, and decisions rendered.

A well-written chart record is valuable in the prevention of duplicative effort. Also, it is the medium through which research is conducted when questions arise as to why certain data were shown on or removed from any issue of the chart.

APPENDICES

APPENDICES

APPENDIX A

ABBREVIATIONS AND SYMBOLS

A more complete listing of abbreviations and symbols is given in H.O. Pub. No. 220, *Navigation Dictionary*, of which this is an abridgment.

A, amplitude; augmentation; away (altitude difference).

a, altitude difference (Ho$\sim$Hc); altitude factor (change of altitude in one minute of time from meridian transit); assumed.

a_0, first Polaris correction.

a_1, second Polaris correction.

a_2, third Polaris correction.

AC, alternating current.

add'l, additional.

AF, audio frequency.

***a*L,** assumed latitude.

AM, amplitude modulation.

AM, ante meridian (before noon).

antilog, antilogarithm.

AP, assumed position.

approx., approximate, approximately.

AU, astronomical unit.

$a\lambda$, assumed longitude.

B, atmospheric pressure correction (altitude); bearing, bearing angle.

B_A, difference between heading and apparent wind direction.

Bn, bearing (as distinguished from bearing angle).

Bpgc, bearing per gyro compass.

B_T, difference between heading and true wind direction.

C, acceleration correction (altitude); Celsius (centigrade); chronometer time; compass (direction); correction; course, course angle.

CB, compass bearing.

CC, compass course.

CCU, chart comparison unit.

CE, chronometer error; compass error.

CH, compass heading.

cm, centimeter, centimeters.

Cn, course (as distinguished from course angle).

co-, the complement of (90° minus).

colog, cologarithm.

corr., correction.

cos, cosine.

cot, cotangent.

cov, coversine.

Cpgc, course per gyro compass.

cps, cycles per second.

csc, cosecant.

CW, continuous wave.

CZn, compass azimuth.

D, deviation; dip (of horizon); distance.

d, declination (astronomical); difference.

d, declination change in one hour.

DC, direct current.

dec., declination.

Dev., deviation.

DG, degaussing.

diff., difference.

dist., distance.

DLo, difference of longitude (arc units).

DR, dead reckoning, dead reckoning position.

DRE, dead reckoning equipment.

DRM, direction of relative movement.

DRT, dead reckoning tracer.

D_s, dip short of horizon.

dur., duration.

dλ, difference of longitude (time units).

E, east.

e, base of Naperian logarithms.

e, eccentricity.

EHF, extremely high frequency.

EP, estimated position.

EPI, electronic position indicator.

Eq.T, equation of time.

ETA, estimated time of arrival.

F, Fahrenheit; fast; longitude factor; phase correction (altitude).

f, latitude factor.

FM, frequency modulation.
ft., foot, feet.
G, Greenwich, Greenwich meridian (upper branch); grid (direction).
g, acceleration due to gravity; Greenwich meridian (lower branch).
GAT, Greenwich apparent time.
GB, grid bearing.
GC, grid course.
GE, gyro error.
GH, grid heading.
GHA, Greenwich hour angle.
GMT, Greenwich mean time.
GP, geographical position.
Gr., Greenwich.
GST, Greenwich sidereal time.
GV, grid variation.
GZn, grid azimuth.
H, high (loran PRR); horizontal intensity of earth's magnetic field; sea tilt correction (altitude).
h, altitude (astronomical); height above sea level.
***ha*,** approximate altitude.
hav, haversine.
Hc, computed altitude.
Hdg., heading.
HE, heeling error; height of eye.
HF, high frequency.
HHW, higher high water.
HLW, higher low water.
H.O., Hydrographic Office.
Ho, observed altitude.
HP, horizontal parallax.
Hp, precomputed altitude.
Hpgc, heading per gyro compass.
hr, rectified altitude.
hr., hour.
hrs., hours.
hs, sextant altitude.
ht, tabulated altitude.
HW, high water.
I, dip (magnetic); instrument correction.
IC, index correction.
in., inch, inches.
int., interval.
ISLW, Indian spring low water.
J, irradiation correction (altitude).
K, Kelvin (temperature); constant of the cone; constant proportional to required length of Flinders bar.
kc, kilocycle, kilocycles; kilocycles per second.
km, kilometer, kilometers.
kmc, kilomegacycle, kilomegacycles; kilomegacycles per second.
kn., knot, knots.
L, latitude; low (loran PRR); lower limb correction for moon (from *Nautical Almanac*); wave length (water).
***l*,** difference of latitude; logarithm, logarithmic.
LAN, local apparent noon.
LAT, local apparent time.
lat., latitude.
LF, low frequency.
LHA, local hour angle.
LHW, lower high water.
LL, lower limb.
LLW, lower low water.
Lm, middle latitude.
LMT, local mean time.
log, logarithm, logarithmic.
$\log_e$, natural logarithm (to the base e).
$\log_{10}$, common logarithm (to the base 10).
long., longitude.
LST, local sidereal time.
LW, low water.
M, celestial body; meridian (upper branch); magnetic (direction); meridional parts; nautical mile, miles.
m, meridian (lower branch); meridional difference ($M_1 \sim M_2$); meter, meters; statute mile, miles.
mag., magnetic; magnitude.
MB, magnetic bearing.
mb, millibar, millibars.
MC, magnetic course.
mc, megacycle, megacycles; megacycles per second.
MF, medium frequency.
MH, magnetic heading.
MHHW, mean higher high water.
MHW, mean high water.
MHWN, mean high water neaps.
MHWS, mean high water springs.
mi., mile, miles.
mid, middle.
min., minute, minutes.
MLLW, mean lower low water.
MLW, mean low water.
MLWN, mean low water neaps.

MLWS, mean low water springs.
mm, millimeter.
mo., month.
mos., months.
mph, miles (statute) per hour.
MPP, most probable position.
MSL, mean sea level.
MZn, magnetic azimuth.
N, north; tilt correction (altitude).
***n*,** natural (trigonometric function).
Na, nadir.
P, atmospheric pressure; parallax; planet; pole; wave period (water).
p, departure, polar distance.
PC, personal correction.
pgc, per gyro compass.
P in A, parallax in altitude.
PM, pulse modulation.
PM, post meridian (after noon).
Pn, north pole; north celestial pole.
PPI, plan position indicator.
PRR, pulse repetition rate.
Ps, south pole; south celestial pole.
psc, per standard compass.
p stg c, per steering compass.
Pub., publication.
PV, prime vertical.
Q, Polaris correction (*Air Almanac*).
QQ′, celestial equator.
R, Rankine (temperature); refraction.
RA, right ascension.
rad, radian, radians.
RAR, radio acoustic ranging.
Ra. Ref., radar reflector.
RB, relative bearing.
R Bn, radiobeacon.
RDF, radio direction finder.
rev., reversed.
RF, radio frequency.
R Fix, running fix.
RZn, relative azimuth.
S, sea-air temperature difference correction (altitude); slow; south; special (loran PRR); speed.
s, ½ (h+L+p); standard deviation.
S_A, speed of apparent wind in units of ship's speed.
SD, semidiameter.
sec, secant.
sec., second, seconds.
semidur., semiduration.
SH, ship's head (heading).
SHA, sidereal hour angle.
SHF, super high frequency.
sin, sine.
SRM, speed of relative movement.
S_T, speed of true wind in units of ship's speed.
T, air temperature correction (altitude); table; temperature; time; toward (altitude difference); true (direction).
t, dry-bulb temperature; elapsed time; meridian angle.
t′, wet-bulb temperature.
tab., table.
tan, tangent.
TB, true bearing; air temperature-atmospheric pressure correction (altitude).
TC, true course.
TcHHW, tropic higher high water.
TcHLW, tropic higher low water.
TcLHW, tropic lower high water.
TcLLW, tropic lower low water.
T_G, ground-wave reading (loran).
T_{GS}, ground-wave–sky-wave reading (loran).
TH, true heading.
TR, track.
Tr., transit.
T_S, sky-wave reading (loran).
T_{SG}, sky-wave–ground-wave reading (loran).
TZn, true azimuth.
U, upper limb correction for moon (from *Nautical Almanac*).
UHF, ultra high frequency.
UL, upper limb.
UT, universal time.
V, deflection of the vertical; variation; vertex.
***v*,** excess of GHA change from adopted value for one hour.
Var., variation.
ver, versine.
VHF, very high frequency.
VLF, very low frequency.
VPR, virtual PPI reflectoscope.
W, watch time; wave-height correction (altitude); west.
WE, watch error.
WT, war time.
X, parallactic angle.

yd., yard.
yds., yards.
yr., year.
yrs., years.
Z, azimuth angle; Coriolis correction (altitude); vertical intensity of earth's magnetic field; zenith.
z, zenith distance.
ZD, zone description.
Zn, azimuth (as distinguished from azimuth angle).
Znpgc, azimuth per gyro compass.
ZT, zone time.
α, damping error (gyro compass).
Δ, a small increment, or the change in one quantity corresponding to unit change in another.
δ, speed error (gyro compass).
λ, longitude; shielding factor; wave length (radiant energy).
μ, index of refraction; permeability.
μs, microsecond.
π, ratio of circumference of circle to diameter$=3.14159+$.

Positions

⊙ Dead reckoning position; fix, running fix.
⊡ Estimated position.

Mathematical Symbols

$+$ Plus (addition)
$-$ Minus (subtraction)

Γ γ	Gamma	Ο ο	Omicron
Δ δ	Delta	Π π ϖ	Pi
Ε ε	Epsilon	Ρ ρ	Rho
Ζ ζ	Zeta	Σ σ ς	Sigma
Η η	Eta	Τ τ	Tau
Θ θ ϑ	Theta	Υ υ	Upsilon
Ι ι	Iota	Φ φ ϕ	Phi
Κ κ	Kappa	Χ χ	Chi
Λ λ	Lambda	Ψ ψ	Psi
Μ μ	Mu	Ω ω	Omega

APPENDIX C

GLOSSARY

This appendix is an abridgment of the definitions of H.O. Pub. No. 220, *Navigation Dictionary*, to which reference should be made for complete definitions.

abeam. Bearing approximately 090° relative (*abeam to starboard*) or 270° relative (*abeam to port*).

aberration. The apparent displacement of a celestial body in the direction of orbital motion of the earth.

abscissa. The horizontal coordinate of a set of rectangular coordinates.

absolute humidity. The mass of water vapor per unit of volume of air.

absolute zero. The lowest possible temperature, about (−) 459°.67 F or (−) 273°.15 C.

aclinic line. The magnetic equator.

acoustic navigation. Sonic navigation.

acute angle. An angle less than 90°.

advance. The distance a vessel moves in its original direction in making a turn.

advanced line of position. A line of position which has been moved forward to allow for the run since the line was established.

advection. Horizontal movement of part of the atmosphere.

age of the moon. The elapsed time, usually expressed in days, since the last new moon.

agonic line. A line connecting points of no magnetic variation.

aground. Touching, resting, or lodged on the bottom.

ahead. Bearing approximately 000° relative.

aid to navigation. A device external to a craft, designed to assist in determination of position of the craft, or of a safe course, or to warn of dangers.

air almanac. A periodical publication of astronomical data designed primarily for air navigation.

air mass. An extensive body of air within which the conditions of temperature and moisture in a horizontal plane are essentially uniform.

air navigation. The navigation of aircraft.

air temperature correction. That sextant altitude correction due to changes in refraction caused by difference between the actual temperature and the standard temperature used in the computation of the refraction table.

alidade. A telescope or other device mounted over a compass, compass repeater, or compass rose, for measuring direction.

alignment. Adjustment of the tuned circuits of electronic equipment for optimum performance, or synchronization of two or more components of an electronic system.

almanac. A periodical publication of astronomical data useful to a navigator.

Alnico. The trade name for an alloy composed principally of aluminum, nickel, cobalt, and iron; used for permanent magnets.

alternating current. An electric current that continually changes in magnitude and periodically reverses polarity.

alternating fixed and flashing light. A fixed light varied at regular intervals by one or more flashes of greater brilliance, with color variations in either the fixed light or flashes, or both.

alternating fixed and group flashing light. A fixed light varied at regular intervals by a group of two or more flashes of greater brilliance, with color variations in either the fixed light or flashes, or both.

alternating flashing light. A light showing one or more flashes with color variations at regular intervals, the duration of light being less than that of darkness.

alternating group flashing light. A light showing groups of flashes with color variations at regular intervals, the duration of light being less than that of darkness.

alternating group occulting light. A light having groups of total eclipses at regular intervals and having color variations, the duration of light being equal to or greater than that of darkness.

alternating light. A light having periodic color variations, particularly one with constant luminous intensity.

alternating occulting light. A light having one or more total eclipses at regular intervals and having color variations, the duration of light being equal to or greater than that of darkness.

altitude. Angular distance above the horizon; the arc of a vertical circle between the horizon and a point on the celestial sphere, measured upward from the horizon.

altitude azimuth. An azimuth determined when altitude, declination, and latitude are known.

altitude circle. Parallel of altitude.

altitude difference. The difference between computed and observed altitudes, or between precomputed and sextant altitudes.

altitude intercept. Altitude difference.

altocumulus. A cloud layer (or patches) within the middle level (mean height 6,500–20,000 ft.) composed of rather flattened globular masses, the smallest elements of the regularly arranged layers being fairly thin, with or without shading. These elements are arranged in groups, in lines or in waves, following one or two directions, and are sometimes so close together that their edges join.

altostratus. A sheet of gray or bluish cloud within the middle level (mean height 6,500–20,000 ft.). Sometimes the sheet is composed of a compact mass of dark, thick, gray clouds of fibrous structure; at other times the sheet is thin and through it the sun or moon can be seen dimly as though gleaming through ground glass.

amplitude. **1.** Angular distance north or south of the prime vertical; the arc of the horizon or the angle at the zenith between the prime vertical and a vertical circle, measured north or south from the prime vertical to the vertical circle. **2.** The maximum value of the displacement of a wave or other periodic phenomenon from the zero position.

amplitude balance. Equality in the amplitude of two or more signals.

amplitude modulation. The process of changing the amplitude of a carrier wave in accordance with the variations of a modulating wave.

anchorage. An area where a vessel anchors or may anchor, either because of suitability or designation.

anchorage buoy. One of a series of buoys marking the limits of an anchorage.

anchorage chart. A nautical chart showing prescribed or recommended anchorages.

anchor buoy. A buoy marking the position of an anchor.

anemometer. An instrument for measuring the speed of the wind. Some instruments also indicate the direction from which it is blowing.

aneroid barometer. An instrument which determines atmospheric pressure by the effect of such pressure on a thin-metal cylinder from which the air has been partly exhausted.

angle. The inclination to each other of two intersecting lines, measured by the arc of a circle intercepted between the two lines forming the angle, the center of the circle being the point of intersection.

angular distance. The angular difference between two directions, or the arc of the great circle joining two points.

anneal. To heat (metal) to a high temperature and then allow to cool slowly, for the purpose of softening, making less brittle, or removing permanent magnetism.

annular. Ring-shaped.

annular eclipse. An eclipse in which a thin ring of the source of light appears around the obscuring body.

anode. The positive pole or electrode of an electron tube or an electric cell.

ante meridian. Before noon.

antenna. A conductor or system of conductors for radiating or receiving radio waves.

antenna array. A group of antennas arranged so as to obtain directional characteristics.

anticyclone. An approximately circular portion of the atmosphere, having relatively high atmospheric pressure and winds which blow clockwise around the center in the northern hemisphere and counterclockwise in the southern hemisphere.

antilogarithm. The number corresponding to a given logarithm.

aperiodic compass. A compass that, after being deflected, returns by one direct movement to its proper reading, without oscillation.

aphelion. That orbital point farthest from the sun when the sun is the center of attraction (as in the case of a planet).

apogean tides. Tides of decreased range occurring when the moon is near apogee.

apogee. That orbital point farthest from the earth when the earth is the center of attraction (as in the case of the moon).

apparent altitude. Rectified altitude.

apparent horizon. Visible horizon.

apparent motion. Motion relative to a specified or implied reference point which may itself be in motion.

apparent sun. The actual sun as it appears in the sky.

apparent time. Time based upon the rotation of the earth relative to the apparent (true) sun.

apparent wind. Wind relative to a moving point, such as a vessel.

approximate altitude. An altitude determined by inexact means, as by estimation or by a star finder or star chart.

arc. **1.** Part of a curved line, as a circle. **2.** The graduated scale of an instrument for measuring angles, as a marine sextant.

arc of visibility. The arc of a light sector, designated by its limiting bearings as observed at points other than the light.

argument. One of the values used for entering a table or diagram.

arm. **1.** An inlet. **2.** A slender part of an instrument, device, or machine.

Armco. The trade name for a high-purity, low-carbon iron, used for Flinders bars, quadrantal correctors, etc.

arming. Tallow or other substance placed in the recess at the lower end of a sounding lead, for obtaining a sample of the bottom.

artificial horizon. A device for indicating the horizontal.

artificial-horizon sextant. A sextant having an artificial horizon built in.

A-scope. A cathode ray scope on which the trace appears as a horizontal or vertical range scale and the signals appear as perpendicular deflections.

assumed latitude. The latitude at which an observer is assumed to be located for an observation or computation.

assumed longitude. The longitude at which an observer is assumed to be located for an observation or computation.

assumed position. A point at which a craft is assumed to be located, particularly one used as a preliminary to establishing certain navigational data, as that point on the surface of the earth for which the computed altitude is determined in the solution of a celestial observation.

astern. Bearing approximately 180° relative.

astrolabe. An instrument used for determining an accurate astronomical position ashore, as in survey work.

astronomical latitude. Angular distance between the direction of gravity and the plane of the equator.

astronomical longitude. The angle between the plane of the reference meridian and the plane of the celestial meridian.

astronomical position. A point on the earth determined by celestial observation.

astronomical refraction. Atmospheric refraction of a ray of radiant energy from outer space.

astronomical tide. Tide related to the attractions of celestial bodies, particularly the sun and moon.

astronomical triangle. The navigational triangle, either terrestrial or celestial, used in the solution of celestial observations.

astronomical twilight. The period of incomplete darkness when the upper limb of the sun is below the visible horizon, and the center of the sun is not more than 18° below the celestial horizon.

astronomical unit. The mean distance between the earth and the sun, approximately 92,900,000 statute miles, used as a unit of measurement of distance within the solar system.

atmosphere. The envelope of air surrounding the earth or other celestial body.

atmospheric absorption. The loss of power in transmission of radiant energy by dissipation in the atmosphere.

atmospheric noise. Static.

atmospheric pressure. The pressure exerted by the weight of the earth's atmosphere. Its standard value at sea level is about 14.7 pounds per square inch.

atmospheric pressure correction. That sextant altitude correction due to changes in refraction caused by nonstandard atmospheric pressure.

atmospheric refraction. Refraction of a ray of radiant energy passing obliquely through the atmosphere.

A trace. The first trace of a scope having more than one, as the upper trace of a loran indicator.

attenuation. A lessening in amount, particularly the reduction of the amplitude of a wave with distance from the origin.

audio frequency. A frequency within the audible range, about 20 to 20,000 cycles per second.

augmentation. The apparent increase in the semidiameter of a celestial body as its altitude increases, due to the decreased distance from the observer.

aural null. A null detected by listening for a minimum or the complete absence of an audible signal.

aurora. A luminous phenomena due to electrical discharge in the upper atmosphere, most commonly seen in high latitudes.

aurora australis. The aurora in the southern hemisphere.

aurora borealis. The aurora in the northern hemisphere.

auroral zone. The area of maximum auroral activity.

automatic celestial navigation. Automatic and continuous indication of position by a device which tracks celestial bodies and solves for geographical coordinates.

automatic radio direction finder. A radio direction finder which indicates automatically and continuously the great-circle direction of the transmitter to which it is tuned.

autumnal equinox. That point of intersection of the ecliptic and the celestial equator occupied by the sun as it changes from north to south declination, on or about September 23, or the instant this occurs.

awash. Situated so that the top is intermittently washed by waves or tidal action.

azimuth. The horizontal direction of a celestial point from a terrestrial point. It is usually measured from 000° at the reference direction clockwise through 360°.

azimuthal equidistant projection. An azimuthal map projection in which distances from the point of tangency are accurately represented according to a uniform scale.

azimuthal projection. A map projection in which the surface of a sphere or spheroid, such as the earth, is conceived as developed on a tangent plane, with the result that azimuths or bearings of any point from the center are correctly represented.

azimuth angle. Azimuth measured from 0° at the north or south reference direction clockwise or counterclockwise through 90° or 180°.

azimuth bar. A slender bar with a vane at each end, designed to fit over a central pivot in the glass cover of a magnetic compass for measurement of compass azimuths.

azimuth circle. A ring designed to fit snugly over a compass or compass repeater, and provided with means for observing compass bearings and azimuths.

azimuth instrument. An instrument for measuring azimuths, particularly a device which fits snugly over a central pivot in the glass cover of a magnetic compass.

azimuth tables. Publications providing tabulated azimuths or azimuth angles.

back. Of the wind, to change direction counterclockwise in the northern hemisphere and clockwise in the southern hemisphere.

back sight. An observation of a celestial body made by facing 180° from the azimuth of the body.

ballistic damping error. That error introduced in a nonpendulous gyro compass as a result of the method used to damp the oscillations of the gyro spin axis.

ballistic deflection error. A temporary error introduced in a gyro compass by the accelerating force acting upon the damping mechanism when a vessel changes course or speed.

bandwidth. The number of units (cycles, kilocycles, etc.) of frequency required for transmission.

barograph. A recording barometer.

barometer. An instrument for measuring atmospheric pressure.

barometric pressure. Atmospheric pressure as indicated by a barometer.

barometric tendency. The change of barometric pressure within a specified time (usually three hours) before an observation, together with the direction of change and the characteristics of the rise or fall.

bar scale. A line or series of lines on a chart, subdivided and labeled with the distances represented on the chart.

base line. **1.** The line between two transmitters operating together to provide a line of position, as in loran. **2.** Any line serving as the basis for measurement of other lines, as in surveying. **3.** The trace of a cathode ray tube.

base line delay. The time interval needed for the signal from a loran master station to travel the length of the base line, introduced as a delay between transmission of the master and slave signals.

base line extension. The extension of a base line beyond the transmitters.

basic pulse repetition rate. The lowest pulse repetition rate of a group differing only slightly from each other.

bathymetric chart. A topographic chart of the bed of a body of water.

bathythermograph. A recording thermometer for determining temperature of the sea at various depths.

Bayer's name. The Greek (or Roman) letter and the possessive form of the Latin name of a constellation, used as a star name.

beacon. **1.** A fixed aid to navigation. **2.** An unlighted aid to navigation. **3.** Anything serving as a signal or conspicuous indication, either for guidance or warning.

beam width. The angular width of a beam of radiant energy between half-power intensities.

bearing. The horizontal direction of one terrestrial point from another. It is usually measured from 000° at the reference direction clockwise through 360°.

bearing angle. Bearing measured from 0° at the north or south reference direction clockwise or counterclockwise through 90° or 180°.

bearing bar. A slender bar with a vane at each end, designed to fit over a central pivot in the glass cover of a magnetic compass, for measurement of compass bearings.

bearing circle. A ring designed to fit snugly over a compass or compass repeater, and provided with vanes for observing compass bearings.

bearing line. A line extending in the direction of a bearing.

bearing repeater. A compass repeater used primarily for observing bearings.

Beaufort scale. A numerical scale for indicating wind speed, named after Admiral Sir Francis Beaufort, who devised it in 1806.

beset. Surrounded so closely by sea ice that steering control is lost.

binnacle. The stand in which a compass is mounted.

blinking. Regular shifting right and left of a loran signal to indicate that the signals are out of synchronization.

blue azimuth tables. H.O. Pub. No. 261, *Azimuths of Celestial Bodies*.

blue magnetism. The magnetism of the south-seeking end of a freely suspended magnet.

boat compass. A small compass mounted in a box for convenient use in small craft.

bobbing a light. Quickly lowering the height of eye several feet and then raising it again when a light is first sighted, to determine whether the observer is at the geographical range of the light.

bottom sample. A portion of the material forming the bottom, brought up for inspection.

bow and beam bearings. Successive relative bearings (right or left) of 45° and 90° of a fixed object.

boxing the compass. Stating in order the names of the points (and sometimes fractional points) of the compass.

broad on the beam. Bearing 090° relative ("broad on the starboard beam") or 270° relative ("broad on the port beam").

broad on the bow. Bearing 045° relative ("broad on the starboard bow") or 315° relative ("broad on the port bow").

broad on the quarter. Bearing 135° relative ("broad on the starboard quarter") or 225° relative ("broad on the port quarter").

B trace. The second trace of a scope having more than one, as the lower trace of a loran indicator.

bubble sextant. A sextant with a bubble to indicate the horizontal.

buoy. A floating object, other than a lightship, moored or anchored to the bottom as an aid to navigation.

buoyage. A system of buoys.

cable. **1.** A unit of distance equal to 720 feet in the U. S. Navy. **2.** A chain or strong fiber or wire rope used to anchor or moor vessels or buoys. **3.** A stranded electric conductor or several conductors laid up together.

cage. To erect a gyro or lock it in place.

calculated altitude. Computed altitude.

calibrate. To determine or rectify the scale graduations of an instrument.

calibration table. A table of calibration corrections or calibrated values.

calving. The breaking away of a mass of ice from a parent iceberg, glacier, or ice shelf.

can buoy. A buoy the above-water part of which is in the shape of a cylinder.

candela. The United States and international unit of luminous intensity.

cardinal point. North, east, south, or west.

carrier wave. A radio wave used as a vehicle for conveying intelligence, generally by modulation.

Cartesian coordinates. Magnitudes defining a point relative to two intersecting lines or *axes*.

cartography. The art and science of making charts or maps.

cathode. The negative pole or electrode of an electron tube or an electric cell.

cathode ray tube. The "picture" tube of radar, loran, television, etc.

C-band. A radio-frequency band of 3,900 to 6,200 megacycles.

celestial body. Any aggregation of matter in space constituting a unit, such as the sun, a planet, etc.

celestial coordinates. Any set of coordinates used to define a point on the celestial sphere.

celestial equator. The intersection of the celestial sphere and the extended plane of the equator.

celestial equator system of coordinates. Declination and hour angle or declination and sidereal hour angle.

celestial fix. A fix established by observation of celestial bodies.

celestial horizon. That great circle of the celestial sphere formed by the intersection of the celestial sphere and a plane through the center of the earth and perpendicular to the zenith-nadir line.

celestial latitude. Angular distance north or south of the ecliptic; the arc of a circle of latitude between the ecliptic and a point on the celestial sphere, measured northward or southward from the ecliptic through 90°, and labeled N or S to indicate the direction of measurement.

celestial line of position. A line of position established by observation of a celestial body.

celestial longitude. Angular distance east of the vernal equinox, along the ecliptic; the arc of the ecliptic or the angle at the ecliptic pole between the circle of latitude of the vernal equinox and the circle of latitude of a point on the celestial sphere, measured eastward from the circle of latitude of the vernal equinox, through 360°.

celestial meridian. A great circle of the celestial sphere, through the celestial poles and the zenith.

celestial navigation. Navigation with the aid of celestial bodies.

celestial observation. Observation of celestial phenomena.

celestial poles. The intersection of the celestial sphere and the extended axis of the earth.

celestial sphere. An imaginary sphere of infinite radius concentric with the earth, on which all celestial bodies except the earth are imagined to be projected.

celestial triangle. A spherical triangle on the celestial sphere, especially the navigational triangle.

Celsius temperature. Temperature based upon a scale in which, under standard atmospheric pressure, water freezes at 0° and boils at 100°. Called "centigrade temperature" before 1948.

centering control. A control used to center the image on a cathode ray tube.

centering error. That instrumental error due to inaccurate pivoting of a moving part.

centigrade temperature. Celsius temperature.

change of tide. A reversal of the direction of motion (rising or falling) of a tide.

characteristics of a light. The sequence and length of light and dark periods and the color or colors by which a navigational light is identified.

character of the bottom. The type of material of which the bottom is composed.

chart. A map intended primarily for navigational use.

chart comparison unit. A device which provides simultaneous, superimposed views of a chart and radar scope.

chart datum. The tidal datum to which soundings on a chart are referred.

charted depth. The vertical distance from the chart datum to the bottom.

charted visibility. The extreme distance, shown in numbers on a chart, at which a navigational light can be seen under standard conditions.

chartlet. **1.** A small chart. **2.** A graphic supplement to *Notice to Mariners*.

chart projection. A map projection used for a chart.

chart reading. Interpretation of the symbols, lines, abbreviations, and terms appearing on charts.

chronometer. A timepiece with a nearly constant rate.

chronometer error. The amount by which chronometer time differs from the correct time to which it was set, usually Greenwich mean time.

chronometer rate. The amount gained or lost by a chronometer in unit time, usually seconds per day.

chronometer time. Time as indicated by a chronometer.

chronometer watch. A small chronometer, especially one with an enlarged watch-type movement.

circle of declination. Hour circle.

circle of equal altitude. A circle on the surface of the earth, on every point of which the altitude of a given celestial body is the same at a given instant.

circle of equal declination. Parallel of declination.

circle of latitude. **1.** A great circle of the celestial sphere, perpendicular to the ecliptic. **2.** A meridian of the earth.

circle of longitude. **1.** A circle of the celestial sphere, parallel to the ecliptic. **2.** A parallel of latitude on the earth.

circle of position. A circular line of position.

circle of right ascension. Hour circle.

circle of uncertainty. A circle within which a craft is considered to be located.

circle of visibility. That circle surrounding an aid to navigation in which the aid is visible.

circumpolar. Revolving about the elevated pole without setting.

cirrocumulus. High clouds (mean lower level above 20,000 ft.) composed of small white flakes or of very small globular masses, usually without shadows, which are arranged in groups or lines, or more often in ripples resembling those of sand on the seashore.

cirrostratus. Thin, whitish, high clouds (mean lower level above 20,000 ft.) sometimes covering the sky completely and giving it a milky appearance and at other times presenting, more or less distinctly, a formation like a tangled web.

cirrus. Detached high clouds (mean lower level above 20,000 ft.) of delicate and fibrous appearance, without shading, generally white in color, and often of a silky appearance.

civil twilight. The period of incomplete darkness when the upper limb of the sun is below the visible horizon, and the center of the sun is not more than 6° below the celestial horizon.

clamp screw. A screw for holding a moving part in place, as during an observation or reading, particularly such a device used in connection with the tangent screw of a marine sextant.

clamp screw sextant. A marine sextant having a clamp screw for controlling the position of the tangent screw.

cloud. A visible assemblage of numerous tiny droplets of water or ice crystals formed by condensation of water vapor in the air, with the base above the surface of the earth.

clutter. Atmospheric noise, extraneous signals, etc., which tend to obscure the reception of a desired signal in a radio receiver, on a radar scope, etc.

coaltitude. Ninety degrees minus the altitude.

coarse delay. On a loran indicator, a dial for controlling relatively large changes in the position of the B trace pedestal.

coastal current. An ocean current flowing roughly parallel to a coast, outside the surf zone.

coastal refraction. A small change in the direction of travel of a radio signal when it crosses a shore line obliquely.

coast chart. A nautical chart intended for use near a shore, as in entering and leaving harbors.

coasting. Proceeding approximately parallel to a coast line and near enough to be in pilot waters most of the time.

coast pilot. A descriptive book for the use of mariners, containing detailed information of coastal waters, harbor facilities, etc., of an area, particularly along the coasts of the United States.

coast piloting. The directing of the movements of a vessel near a coast, by means of terrestrial reference points.

coastwise navigation. Navigation in the vicinity of a coast.

codeclination. Ninety degrees minus the declination.

coding delay. An arbitrary time delay in the transmission of pulse signals.

colatitude. Ninety degrees minus the latitude.

cold air mass. An air mass that is colder than surrounding air, and usually colder than the surface over which it is moving.

cold front. That line of discontinuity, at the earth's surface or at a horizontal plane aloft, along which an advancing cold air mass is undermining and displacing a warmer air mass.

collision bearing. A constant bearing maintained while the distance between two craft is decreasing.

cologarithm. The logarithm of the reciprocal of a number.

combination buoy. A buoy having more than one means of conveying intelligence, as by light and sound.

comparing watch. A hack watch having its error determined by comparison with a chronometer.

compass. An instrument for determining a horizontal reference direction relative to the earth.

compass adjustment. The process of neutralizing the magnetic effect a vessel exerts on a magnetic compass.

compass amplitude. Amplitude relative to compass east or west.

compass azimuth. Azimuth relative to compass north.

compass bearing. Bearing relative to compass north.

compass bowl. That part of a compass in which the compass card is mounted.

compass card. That part of a compass on which the direction graduations are placed.

compass compensation. The process of neutralizing the effects which degaussing currents exert on a marine magnetic compass.

compass course. Course relative to compass north.

compass error. The angular difference between a compass direction and the corresponding true direction.

compasses. An instrument for drawing circles.

compass heading. Heading relative to compass north.

compass north. The direction north as indicated by a magnetic compass.

compass points. The 32 divisions of a compass, at intervals of $11\frac{1}{4}°$.

compass repeater. That part of a remote-indicating compass system which repeats at a distance the indications of the master compass.

compass rose. A circle graduated in degrees, clockwise from 0° at the reference direction to 360°, or in compass points, or in both degrees and points.

complement. An angle equal to 90° minus the given angle.

composite sailing. A modification of great-circle sailing used when it is desired to limit the highest latitude.

computed altitude. Altitude of the center of a celestial body above the celestial horizon at a given time and place, as determined by computation, table, mechanical device, or graphics.

computed point. The foot of a perpendicular from a dead reckoning position to a celestial line of position.

conformal projection. A map projection in which all angles around any point are correctly represented.

conic projection. A map projection in which the surface of a sphere or spheroid, such as the earth, is conceived as developed on one or more cones which are then spread out to form a plane.

conjunction. The situation of two celestial bodies having either the same celestial longitude or the same sidereal hour angle.

consol. An electronic navigational system providing a number of rotating equisignal zones that permit determination of bearings from a transmitting station by counting a series of dots and dashes and referring to a table or special chart.

constant error. A systematic error of unchanging magnitude and sign.

constellation. Originally, a conspicuous configuration of stars; now, a region of the celestial sphere marked by arbitrary boundary lines.

continuous wave. A series of waves of like amplitude and frequency.

contour. A line connecting points of equal elevation or equal depth.

contrary name. A name (such as north or south) opposite or contrary to that of something else. Usually used in connection with declination and latitude.

controlling depth. The least depth in the approach or channel to an area, such as a port, governing the maximum draft of vessels that can enter.

convergence constant. The angle at a given latitude between meridians 1° apart.

conversion angle. The angle between the rhumb line and the great circle between two points.

coordinate. One of a set of magnitudes defining a point in space.

Coriolis force. An apparent force acting on a body in motion, due to rotation of the earth, causing deflection to the right in the northern hemisphere and to the left in the southern hemisphere.

corner reflector. A combination of mutually intersecting, conducting surfaces designed to return electromagnetic radiations toward their sources, and used primarily to render objects more conspicuous to radar observations.

correcting. The process of applying corrections, particularly compass corrections.

corrector. A magnet, piece of soft iron, or device used in the adjustment or compensation of a magnetic compass.

countercurrent. A secondary current flowing adjacent and in the opposite direction to another current.

course. The intended horizontal direction of travel. It is usually measured from 000° at the reference direction clockwise through 360°.

course angle. Course measured from 0° at the reference direction clockwise or counterclockwise through 90° or 180°.

course error. Angular difference between the course and the course made good.

course line. **1.** A line extending in the direction of a given course. **2.** A line of position approximately parallel to the course.

course made good. The direction of a point of arrival from a point of departure.

course of advance. The course expected to be made good over the ground.

course over the ground. The course actually made good over the ground.

course recorder. A device which records the headings of a vessel.

critical range. The spread of ranges in which there is an element of uncertainty in interpretation, as in the case of ground waves and sky waves of loran.

critical table. A table in which values of the quantity to be found are tabulated for limiting values of the entering argument.

cross bearings. Two or more bearings used as intersecting lines of position for fixing the position of a vessel.

culmination. Meridian transit.

culture. Map details which represent cultural features, such as cities, railroads, aids to navigation, latitude and longitude lines, etc., as contrasted with natural features.

cumulonimbus. A massive cloud with great vertical development, the summits of which rise in the form of mountains or towers, the upper parts often spreading out in the form of an anvil.

cumulus. A dense cloud with vertical development, having a horizontal base and dome-shaped upper surface, exhibiting protuberances.

current. **1.** Water in essentially horizontal motion. **2.** A hypothetical horizontal motion of such set and drift as to account for the difference between a dead reckoning position and a fix at the same time. **3.** Air in essentially vertical motion. **4.** Electricity flowing along a conductor.

current chart. A chart on which current data are graphically depicted.

current diagram. A graph showing the average speeds of flood and ebb currents throughout the current cycle for a considerable part of a tidal waterway.

current difference. The difference between the time of slack water or strength of current at a subordinate station and at its reference station.

current direction. The direction *toward* which a current is flowing.

current meter. An instrument for measuring the speed of a current, and sometimes the direction of flow, also.

current rips. Small waves formed on the surface of water by the meeting of opposing ocean currents.

cursor. A device used with an instrument, to provide a movable reference.

cut. The intersection of lines of position, constituting a fix, with particular reference to the angle of intersection.

cyclone. An approximately circular portion of the atmosphere, having relatively low atmospheric pressure and winds which blow counterclockwise around the center in the northern hemisphere and clockwise in the southern hemisphere.

cylindrical buoy. Can buoy.

cylindrical projection. A map projection in which the surface of a sphere or spheroid, such as the earth, is conceived as developed on a tangent cylinder, which is then spread out to form a plane.

daily rate. The change in chronometer error or watch error in 24 hours.

damping. The progressive diminishing of amplitude of oscillations, waves, etc.

dan buoy. A buoy consisting of a ballasted float carrying a staff which supports a flag or light.

danger angle. The maximum or minimum angle between two points (separated either horizontally or vertically), as observed from a vessel, indicating the limit of safe approach to an off-lying danger.

danger bearing. The maximum or minimum bearing of a point for safe passage past an off-lying danger.

danger buoy. A buoy marking an isolated danger to navigation.

danger line. A line drawn on a chart, to indicate the limits of safe navigation for a vessel of specific draft.

dangerous semicircle. That half of a cyclonic storm area to the *right* of the storm track in the northern hemisphere, and to the *left* of the storm track in the southern hemisphere. In this semicircle the winds are stronger and tend to blow a vessel into the path of the storm.

danger sounding. A minimum sounding chosen for a vessel of specific draft in a given area to indicate the limit of safe navigation.

date line. The boundary between the (−)12 and (+)12 time zones, corresponding approximately with the 180th meridian.

datum. The base value, level, direction, or position from which any quantity is measured.

daybeacon. An unlighted beacon.

daylight saving time. A variation of zone time, usually one hour later than standard time.

daymark. A distinctive structure serving as an aid to navigation during daylight, whether or not the structure has a light.

day's run. The distance traveled by a vessel in one day, usually reckoned from noon to noon.

day's work. The daily routine of the navigation of a vessel at sea.

dead ahead. Bearing 000° relative.

dead astern. Bearing 180° relative.

deadbeat compass. Aperiodic compass.

dead reckoning. Determination of position by advancing a previous position for courses and distances.

dead reckoning equipment. A device that continuously indicates the dead reckoning position of a vessel.

dead reckoning plot. A plot of the movements of a craft as determined by dead reckoning.

dead reckoning position. A position determined by dead reckoning.

dead reckoning tracer. A device that automatically provides a graphical record of the dead reckoning track.

dead reckoning track. A line representing successive dead reckoning positions of a craft.

Decca. An electronic navigational system by which hyperbolic lines of position are determined by measuring the phase difference of synchronized continuous wave signals.

decibel. A unit for expressing the loudness of sounds, one decibel being approximately the least change detectable by the average human ear.

deck log. A written record of the movements of a vessel with regard to courses, speeds, positions, and other navigational information, and important events aboard the vessel.

declination. Angular distance north or south of the celestial equator; the arc of an hour circle between the celestial equator and a point on the celestial sphere, measured northward or southward from the celestial equator through 90°, and labeled N or S to indicate the direction of measurement.

deep. An unmarked fathom point on a lead line.

deep sea lead (lĕd). A heavy sounding lead (about 30 to 100 pounds), usually having a line 100 fathoms or more in length.

deflection of the vertical. The angular difference between the direction of a plumb line (the vertical) and the perpendicular (the normal) to the reference spheroid.

deflector. An instrument for measuring the relative directive force acting on a magnetic compass on different headings, for use in compass adjustment.

degaussing. Neutralization of the strength of the magnetic field of a vessel, by means of suitably arranged electric coils permanently installed in the vessel.

demodulation. The process of obtaining a modulating wave from a modulated wave.

departure. **1.** The distance between two meridians at any given parallel of latitude, expressed in linear units, or the distance to the east or west made good by a vessel in proceeding from one point to another. **2.** Act of departing or leaving.

deperming. The process of changing the magnetic condition of a vessel by wrapping a large conductor around it a number of times in a vertical plane, athwartships, and energizing the coil thus formed.

depressed pole. That celestial pole below the horizon, of contrary name to the latitude.

depth. Vertical distance from a given water level to the bottom.

depth contour. A contour connecting points of equal depth.

destination. The point of intended arrival.

deviation. The angle between the magnetic meridian and the axis of a compass card.

deviation table. A table of the deviation of a magnetic compass on various headings.

dew point. The temperature to which air must be cooled at constant pressure and constant water vapor content to reach saturation.

diagram on the plane of the celestial meridian. A diagram in which the local celestial meridian appears as a circle with the zenith at the top, and the horizon as a horizontal diameter.

diaphone. A device for producing a distinctive fog signal by means of a slotted reciprocating piston actuated by compressed air.

difference of latitude. The shorter arc of any meridian between the parallels of two places, expressed in angular measure.

difference of longitude. The smaller angle at the pole or the shorter arc of a parallel between the meridians of two places, expressed in angular measure.

dip. 1. The vertical angle, at the eye of an observer, between the horizontal and the line of sight to the visible horizon. **2.** The angle between the horizontal and the lines of force of the earth's magnetic field. **3.** The first detectable decrease in the altitude of a celestial body after reaching its maximum at or near meridian transit.

dip circle. An instrument for measuring magnetic dip.

dip correction. That correction to a sextant altitude due to dip of the horizon.

dip needle. A magnetized needle mounted so as to indicate magnetic dip.

dip of the horizon. Dip, definition 1.

direct current. An electric current which flows continuously in the same direction.

direction. The position of one point in space relative to another without reference to the distance between them.

direction finder deviation. Error in the reading of a radio direction finder due to its environment.

direction of current. The direction *toward* which a current is flowing.

direction of waves or swell. The direction *from* which waves or swell are moving.

direction of wind. The direction *from* which a wind is blowing.

directive force. The force tending to cause the directive element of a compass to line up with the reference direction.

direct wave. A radio wave which travels from transmitter to receiver without an abrupt change due to refraction or reflection.

disposition of lights. The arrangement, order, etc., of navigational lights in an area.

distance finding station. A radiobeacon with a synchronized sound signal.

distance marker. A device indicating distance, particularly one on a radar indicator.

diurnal. Having a period of, occurring in, or related to a day.

diurnal circle. The apparent daily path of a celestial body.

diurnal current. Tidal current having one flood current and one ebb current each tidal day.

diurnal inequality. The difference between the heights of the two high tides or two low tides during the tidal day, or the difference in speed between the two flood currents or the two ebb currents during a tidal day.

diurnal motion. The apparent daily motion of a celestial body.

diurnal tide. Tide having one high tide and one low tide each tidal day.

dividers. An instrument consisting in its simple form of two pointed legs joined by a pivot, used principally for measuring distances or coordinates.

dock. The space between two piers, or a basin or enclosure for reception of vessels and controlling the water level.

Doppler effect. The apparent change in frequency of radiant energy when the distance between the source and the observer or receiver is changing.

double. To travel around with a near reversal of course, as to *double a cape*.

double pulsing. The transmitting of loran signals of two rates by a single station.

double tide. A high tide consisting of two maxima of nearly the same height separated by a relatively small depression, or a low tide consisting of two minima separated by a relatively small elevation.

doubling the angle on the bow. A method of obtaining a running fix by measuring the distance a vessel travels while the relative bearing (right or left) of a fixed object doubles.

draft. The depth to which a vessel is submerged.

drafting machine. An instrument consisting essentially of a protractor and one or more arms attached to a parallel motion device.

drift. **1.** The speed of a current. **2.** The distance a vessel is moved by current and wind. **3.** Downwind or downcurrent motion due to wind or current.

drift current. Any broad, shallow, slow-moving ocean current.

drift lead. A lead placed on the bottom to indicate movement of a vessel.

drogue. Sea anchor.

dry compass. A compass without a liquid-filled bowl.

dumb compass. Pelorus.

earth inductor compass. A compass depending for its indications upon the current generated in a coil revolving in the earth's magnetic field.

easting. The distance a craft makes good to the east.

ebb current. Tidal current moving away from land or down a tidal stream.

echo ranging. Determination of distance by measuring the time interval between transmission of a radiant energy signal, usually sound, and the return of its echo.

echo sounder. An instrument used for echo sounding.

echo sounding. Determination of the depth of water by measuring the time interval between emission of a sonic or ultrasonic signal and the return of its echo from the bottom.

eclipse. The obscuration of a source of light by the intervention of an object.

ecliptic. The apparent annual path of the sun among the stars.

ecliptic diagram. A diagram of the zodiac, indicating the positions of certain celestial bodies in this region.

ecliptic pole. On the celestial sphere, either of the two points 90° from the ecliptic.

ecliptic system of coordinates. Celestial latitude and celestial longitude.

electrode. A terminal at which electricity passes from one medium into another.

electromagnetic energy. Radiant energy in radio waves, light waves, X-rays, heat waves, etc.

electronic navigation. Navigation by means of electronic equipment.

electronics. The science and technology relating to the emission, flow, and effects of electrons in a vacuum or through a semiconductor such as a gas, and to systems using devices in which this action takes place.

elevated pole. That celestial pole above the horizon, of the same name as the latitude.

***E*-link.** A bracket attached to one of the arms of a binnacle to permit the mounting of a quadrantal corrector in an intermediate position between the fore-and-aft and athwartship lines through a magnetic compass.

ellipsoid. A surface whose cross-sections are all ellipses or circles, or the solid enclosed by such a surface.

endless tangent screw. A tangent screw which can be moved over the entire range of its arc without resetting.

engine revolution counter. An instrument for registering the number of revolutions of a propeller shaft.

ephemeris. An almanac for astronomers.

epoch. A particular instant for which certain data are given.

equal altitudes. Two altitudes numerically the same.

equation of time. Apparent time minus mean time (U. S. usage).

equator. The primary great circle of the earth, or a similar body, perpendicular to the polar axis.

equatorial chart. A chart of equatorial areas or one on an equatorial projection.

equatorial projection. A map projection centered on the equator.

equatorial tides. The tides that occur when the moon is near the celestial equator, when the difference in height between consecutive high or low tides is a minimum.

equinoctial. Celestial equator.

equinoctial tides. The tides that occur at or about the time of the equinoxes, when the spring range is greater than average.

equinox. One of the two points of intersection of the ecliptic and the celestial equator, or the instant the sun occupies one of these points, when its declination is 0°.

error of perpendicularity. That error in the reading of a marine sextant due to nonperpendicularity of the index mirror to the frame.

establishment. The interval of time between the transit (upper or lower) of the moon and the next high water.

estimated position. The most probable position of a craft, determined from incomplete data or data of questionable accuracy.

excess of arc. That part of a sextant arc indicating negative readings.

ex-meridian observation. Measurement of the altitude of a celestial body near the celestial meridian, for conversion to an equivalent meridian altitude; or the altitude so measured.

explement. An angle equal to 360° minus the given angle.

extrapolation. The process of estimating the value of a quantity beyond the limits of known values by assuming that the rate or system of change continues.

extremely high frequency. Radio frequency of 30,000 to 300,000 megacycles per second.

eye of the storm. The center of a tropical cyclone.

fade. Of a radiant energy signal, to decrease, often temporarily, in strength without a change of receiver controls.

Fahrenheit temperature. Temperature based upon a scale in which, under standard atmospheric pressure, water freezes at 32° and boils at 212°.

fair tide. A tidal current which increases the speed of a vessel.

fair wind. A wind which aids a craft in making progress in a desired direction.

falling tide. A tide in which the depth of water is decreasing.

false horizon. A line resembling the visible horizon but above or below it.

far vane. That instrument sighting vane on the opposite side of the instrument from the observer's eye.

fata morgana. A complex mirage, characterized by marked distortion, generally in the vertical.

fathom. A unit of length equal to six feet.

fathom curve, fathom line. A depth contour with depth measured in fathoms.

Fathometer. The trade name for a widely used echo sounder.

favorable current. A current which increases the speed of a vessel over the ground.

favorable wind. A wind which helps a craft make progress in a desired direction.

feel the bottom. The action of a vessel in shoal water, when its speed is reduced and it sometimes becomes hard to steer.

fictitious craft. An imaginary craft used in the solution of certain maneuvering problems.

fictitious latitude, fictitious longitude. Coordinates based upon a set of fictitious parallels and fictitious meridians similar to the geographical graticule, but offset from it. These are usually used with a transverse or oblique map projection, or with a navigational grid.

fictitious rhumb line. A line making the same oblique angle with all fictitious meridians.

final great-circle course. The great-circle course at the destination.

fine delay. A dial on a loran indicator, for controlling relatively small changes in the position of the B trace pedestal.

first estimate-second estimate method. The process of determining the value of a variable quantity by trial and error. Used particularly for finding the time of meridian transit at a moving craft.

first point of Aries. Vernal equinox.

fish stakes. Poles or stakes placed in shallow water to outline fishing areas, or to support fish nets.

fix. A relatively accurate position determined without reference to any former position.

fixed and flashing light. A fixed light varied at regular intervals by one or more flashes of greater brilliance.

fixed and group flashing light. A fixed light varied at regular intervals by a group of two or more flashes of greater brilliance.

fixed light. A light having constant luminous intensity.

flashing. The process of reducing the amount of permanent magnetism in a vessel by placing a single coil horizontally around the vessel and energizing the coil.

flashing light. A light showing one or more flashes at regular intervals, the duration of light being less than that of darkness.

Flinders bar. A bar of soft unmagnetized iron placed in a vertical position near a magnetic compass to counteract deviation caused by magnetic induction in vertical soft iron of the craft.

float chamber. A sealed, hollow part attached to the compass card of a magnetic compass as part of the compass card assembly.

floe. Sea ice, either a single unbroken piece or many individual pieces, covering an area of water.

floeberg. A mass of heavily hummocked sea ice resembling an iceberg in appearance.

flood current. Tidal current moving toward land or up a tidal stream.

focal length. The distance between the optical center of a lens, or the surface of a mirror, and its focus.

focal point. Focus.

focus (*pl. foci*). That point at which parallel rays of light meet after being refracted by a lens or reflected by a mirror.

fog. A visible assemblage of numerous tiny droplets of water, or ice crystals formed by condensation of water vapor in the air, with the base at the surface of the earth.

fog signal. A warning signal transmitted by a vessel or aid to navigation during periods of low visibility.

form line. An approximation of a contour without a definite elevation value.

foul berth. A berth in which a vessel at anchor is in danger of striking or fouling another vessel, the ground, or an obstruction.

four-point bearing. A relative bearing of 045° or 315°.

frequency. The rate at which a cycle is repeated.

frequency modulation. The process of changing the frequency of a carrier wave in accordance with the variations of a modulating wave.

front. The intersection of a frontal surface and a horizontal plane.

frontal surface. The thin zone of discontinuity between two air masses.

frost smoke. Fog produced by apparent steaming of a relatively warm sea in the presence of much colder air.

gain. The ratio of output voltage, current, or power to input voltage, current, or power in electronic equipment.

galaxy. A vast assemblage of stars, nebulae, etc., composing an island universe.

gas buoy. A buoy having a gas light.

gauss. The centimeter-gram-second electromagnetic unit of magnetic induction.

Gaussin error. Deviation of a magnetic compass due to transient magnetism which remains in a vessel's structure for short periods after the inducing force has been removed.

gee. An electronic navigation system providing hyperbolic lines of position similar to those of loran.

general chart. A nautical chart intended for offshore coastwise navigation.

geocentric latitude. The angle between the plane of the equator and a line from a point on the surface of the earth to the center of the earth.

geocentric parallax. The difference in the apparent direction or position of a celestial body as observed from the center of the earth and a point on its surface.

geodesic line. The shortest line, on a mathematically derived surface, between two points on that surface.

geodesy. That science which deals mathematically with the size and shape of the earth, and with surveys in which this is considered.

geodetic latitude. The angle between the plane of the equator and a normal to the spheroid.

geodetic line. A geodesic line on the spheroidal earth.

geodetic longitude. The angle between the plane of the prime meridian and the plane through the polar axis and a normal to the spheroid.

geodetic survey. A survey which takes into account the size and shape of the earth.

geographical mile. The length of one minute of arc of the equator, or 6087.090 feet (on the Clarke spheroid of 1866).

geographical position. **1.** That point on the earth at which a given celestial body is in the zenith at a specified time. **2.** Any position on the earth defined by means of its geographical coordinates.

geographic latitude. Geodetic latitude.

geographic longitude. Geodetic longitude.

geographic range. The extreme distance at which an object or light can be seen when limited by the curvature of the earth and the heights of the object and the observer.

geoid. The figure of the earth as defined by mean sea level over the entire surface of the earth.

geoidal horizon. That circle of the celestial sphere formed by the intersection of the celestial sphere and a plane through a point on the sea-level surface of the earth, and perpendicular to the zenith-nadir line.

geomagnetic electrokinetograph. A device for measurement of the lateral component of the speed of an ocean current by means of two pairs of electrodes towed astern.

geomagnetic equator. That terrestrial great circle everywhere 90° from the geomagnetic poles.

geomagnetic pole. Either of two points marking the intersection of the earth's surface with the extended axis of a hypothetical bar magnet at the center of the earth and approximating the source of the actual magnetic field of the earth.

geomagnetism. The magnetism of the earth.

geometrical dip. The vertical angle, at the eye of an observer, between the horizontal and a straight line tangent to the surface of the earth.

geometrical horizon. Originally, the celestial horizon; now more commonly the intersection of the celestial sphere and a cone tangent to the surface of the earth and with its apex at the eye of the observer.

geometric projection. Perspective projection.

ghost. **1.** A radar signal the origin of which cannot readily be determined. **2.** A signal, on a scope, which is not repeated each time a trace is made.

gibbous. Bounded by convex curves.

gimballing error. That error introduced in a gyro compass by the tilting of the gimbal mounting system due to horizontal acceleration, as during a roll.

gimbals. A device for supporting anything, such as an instrument, in such a manner that it remains essentially horizontal when the support tilts.

glacier. A field or stream of ice which moves or has moved slowly down an incline.

gnomonic projection. A map projection in which points on the surface of a sphere or spheroid, such as the earth, are conceived as projected by radials from the center to a tangent plane.

goniometer. An instrument for measuring angles.

gradient. The change of any quantity with distance in any given direction.

gradient tints. A series of color tints used on some charts to indicate relative heights or depths.

graduation error. Inaccuracy in the graduations of the scale of an instrument.

graph. A diagram indicating the relationship between two or more variables.

grass. Sharp, closely spaced deflections of the trace of a cathode ray tube, produced by random interference.

graticule. The network of lines representing parallels and meridians on a map, chart, or plotting sheet.

great circle. The intersection of a sphere and a plane through its center.

great-circle bearing. The initial direction of a great circle through two terrestrial points.

great-circle chart. A chart on which a great circle appears as a straight line or approximately so, particularly a chart on the gnomonic projection.

great-circle course. The direction of the great circle through the point of departure and the destination.

great-circle distance. The length of the shorter arc of the great circle joining two points.

great-circle sailing. Any method of solving the various problems involving courses, distances, etc., as they relate to a great-circle track.

great-circle track. The track of a craft following a great circle, or a great circle which it is intended a craft will follow approximately.

greater ebb. The stronger of two ebb currents occurring during a tidal day.

greater flood. The stronger of two flood currents occurring during a tidal day.

greatest elongation. The maximum angular distance of a body of the solar system from the sun, as observed from the earth.

Greenwich apparent time. Local apparent time at the Greenwich meridian; the arc of the celestial equator, or the angle at the celestial pole, between the lower branch of the Greenwich celestial meridian and the hour circle of the apparent (true) sun, measured westward from the lower branch of the Greenwich celestial meridian through 24 hours; Greenwich hour angle of the apparent or true sun, expressed in time units, plus 12 hours.

Greenwich civil time. Greenwich mean time.

Greenwich hour angle. Local hour angle at the Greenwich meridian; angular distance west of the Greenwich celestial meridian; the arc of the celestial equator, or the angle at the celestial pole, between the upper branch of the Greenwich celestial meridian and the hour circle of a point on the celestial sphere, measured westward from the Greenwich celestial meridian through 360°.

Greenwich mean time. Local mean time at the Greenwich meridian; the arc of the celestial equator, or the angle at the celestial pole, between the lower branch of the Greenwich celestial meridian and the hour circle of the mean sun, measured westward from the lower branch of the Greenwich celestial meridian through 24 hours; Greenwich hour angle of the mean sun, expressed in time units, plus 12 hours.

Greenwich meridian. The meridian through Greenwich, England, serving as the prime meridian and the reference meridan for Greenwich time.

Greenwich sidereal time. Local sidereal time at the Greenwich meridian; the arc of the celestial equator, or the angle at the celestial pole, between the upper branch of the Greenwich celestial meridian and the hour circle of the vernal equinox, measured westward from the upper branch of the Greenwich celestial meridian through 24 hours; Greenwich hour angle of the vernal equinox, expressed in time units.

grid. **1.** A series of lines, usually straight and parallel, superimposed on a chart or plotting sheet to serve as a directional reference for navigation. **2.** Two sets of mutually perpendicular lines dividing a map or chart into squares or rectangles to permit location of any point by a system of rectangular coordinates.

grid amplitude. Amplitude relative to grid east or grid west.

grid azimuth. Azimuth relative to grid north.

grid bearing. Bearing relative to grid north.

grid course. Course relative to grid north.

grid declination. The angular difference between grid north and true north.

grid heading. Heading relative to grid north.

grid latitude. Fictitious latitude on a navigational grid.

grid longitude. Fictitious longitude on a navigational grid.

grid navigation. Navigation by the use of grid directions.

grid north. An arbitrary reference direction used with grid navigation.

grid variation. The angular difference between magnetic north and grid north.

grivation. Grid variation.

grounding. The touching of the bottom by a vessel.

ground swell. A long ocean wave, or series of waves, in shoal water, at a considerable distance from its origin.

ground tackle. The anchors, anchor chains, fittings, etc., used for anchoring a vessel.

ground wave. That portion of a radio wave in proximity to and affected by the ground.

group flashing light. A light showing groups of flashes at regular intervals, the duration of light being less than that of darkness.

group occulting light. A light having groups of eclipses at regular intervals, the duration of light being equal to or greater than that of darkness.

growler. A small iceberg, piece broken from an iceberg, or detached piece of sea ice, large enough to be a hazard to shipping but small enough that it may escape detection.

gyro compass. A compass having one or more gyroscopes as the directive element, and tending to indicate true north.

gyro error. The error in the reading of the gyro compass.

gyro pilot. An automatic device for steering a vessel by means of control signals from a gyro compass.

gyro repeater. That part of a remote-indicating gyro compass system which repeats at a distance the indications of the master gyro compass.

gyro sextant. A sextant provided with a gyroscope to indicate the horizontal.

hachures. Short lines on maps or charts, to indicate the slope of the ground.

hack watch. A watch used for timing observations of celestial bodies, regulating ship's clocks, etc.

half pulse repetition rate delay. An interval of time equal to half the pulse repetition rate of a pair of loran transmitters, introduced as a delay between transmission of the master and slave signals.

half-tide level. The level midway between mean high water and mean low water.

hand lead (lĕd). A light sounding lead (7 to 14 pounds), usually having a line of not more than 25 fathoms.

harbor chart. A nautical chart intended for navigation and anchorage in harbors and smaller waterways.

hard iron. Iron or steel which is not readily magnetized by induction, but which retains a high percentage of the magnetism acquired.

haul. Of the wind, to shift in a counterclockwise direction, or to shift forward of a vessel.

haversine. Half of the versine, or $\frac{1-\cos}{2}$.

haze. Fine dust or salt particles in the air, too small to be individually apparent but in sufficient number to reduce visibility and cast a bluish or yellowish veil over the landscape, subduing its colors.

heading. The horizontal direction in which a craft is pointed. It is usually measured from 000° at the reference direction clockwise through 360°.

heading angle. Heading measured from 0° at the reference direction clockwise or counterclockwise through 90° or 180°.

heading line. A line extending in the direction of a heading.

heading-upward plan position indicator. A plan position indicator with the heading of the craft maintained at the top of the indicator.

headway. Motion in a forward direction.

heel. Lateral inclination, as of a vessel during a roll or when listed.

heeling adjuster. A dip needle with a sliding weight that can be moved along one of its arms to balance the magnetic force, used to determine the correct position of a heeling magnet.

heeling error. The change in the deviation of a magnetic compass when a craft heels.

heeling magnet. A permanent magnet placed vertically in a tube under the center of a magnetic compass, to correct for heeling error.

height of eye correction. That correction to sextant altitude due to dip of the horizon.

height of tide. Vertical distance from the tidal datum to the level of the water at any time.

heliocentric parallax. The difference in the apparent positions of a celestial body outside the solar system, as observed from the earth and sun.

high altitude method. The establishing of a circular line of position from the observation of the altitude of a celestial body by means of the geographical position and zenith distance of the body.

higher high water. The higher of two high tides occurring during a tidal day.

higher low water. The higher of two low tides occurring during a tidal day.

high frequency. Radio frequency of three to 30 megacycles per second.

high tide. The maximum height reached by a rising tide.

high water. High tide.

high water full and change. The average interval of time between the transit (upper or lower) of the full or new moon and the next high water.

high water inequality. The difference between the height of the two high tides during a tidal day.

high water lunitidal interval. The interval of time between the transit (upper or lower) of the moon and the next high water at a place.

hiran. High precision shoran.

homing. Navigation toward a point by maintaining constant some navigational coordinate(s), usually bearing.

hop. Travel of a radio wave to the ionosphere and back to earth.

horizon. That great circle of the celestial sphere midway between the zenith and nadir, or a line resembling or approximating such a circle.

horizon glass. That glass of a marine sextant attached to the frame, through which the horizon is observed.

horizon system of coordinates. Altitude and azimuth or altitude and azimuth angle.

horizontal parallax. The geocentric parallax of a celestial body on the celestial horizon.

hour angle. Angular distance west of a celestial meridian or hour circle; the arc of the celestial equator, or the angle at the celestial pole, between the upper branch of a celestial meridian or hour circle and the hour circle of a point on the celestial sphere, measured westward through 360°.

hour circle. On the celestial sphere, a great circle through the celestial poles.

humidity. The amount of water vapor in the air.

hummock. A mound or hill in pressure ice.

hunting. Fluctuation about a mid-point, due to instability, as oscillation of the needle of an instrument about the zero point.

hydrographic survey. A survey of a water area.

hydrography. That science which deals with the measurement of the physical features of waters and their marginal land areas, with special reference to the elements that affect safe navigation, and the publication of such information in a form suitable for use of navigators.

hydrolant. An urgent notice of dangers to navigation in the Atlantic.

hydrometeor. Any product from the condensation of atmospheric water vapor, whether formed in the free atmosphere or at the earth's surface.

hydropac. An urgent notice of dangers to navigation in the Pacific.

hydrophone. A listening device for receiving underwater sounds.

hygrometer. An instrument for measuring the humidity of the air.

hyperbolic line of position. A line of position determined by measuring the difference in distance to two fixed points.

hypsometric tints. Gradient tints.

ice anchor. An anchor used for securing a vessel to ice.

ice barrier. Impenetrable ice.

iceberg. A mass of land ice which has broken away from its parent formation on the coast and either floats in the sea or is stranded.

ice buoy. A sturdy buoy, usually a metal spar, used to replace a more easily damaged buoy during a period when heavy ice is anticipated.

ice chart. A chart showing prevalence of ice, usually with reference to navigable waters.

ice field. Sea ice covering an area greater than five miles across.

ice jam. An accumulation of broken ice caught in a narrow part of a stream or blown against the shore of a lake.

ice shelf. A thick ice formation with level surface extending over the sea but attached to the land.

ice tongue. A narrow peninsula of ice.

index chart. An outline chart showing the limits and identifying designations of charts, volumes of sailing directions, etc.

index correction. That correction due to index error.

index error. That error in the reading of an instrument equal to the difference between the zero of the scale and the zero of the index.

index mirror. That mirror attached to the index arm of a marine sextant.

indirect wave. Any wave which arrives by an indirect path, having undergone an abrupt change of direction by refraction or reflection.

induced magnetism. Magnetism acquired by a piece of magnetic material while it is in a magnetic field.

inertial navigation. Dead reckoning performed automatically by a device which gives a continuous indication of position by double integration of accelerations since leaving a starting point.

infrared. Having a frequency immediately beyond the red end of the visible spectrum.

initial great-circle course. The great-circle course at the point of departure.

inshore. In or near the shore.

installation error. That error of an instrument reading due to incorrect installation of the instrument.

instrument error. The inaccuracy of an instrument due to imperfections within the instrument.

instrument shelter. A cage or screen in which a thermometer and sometimes other instruments are placed to shield them from conditions that would interfere with registration of true conditions.

intercardinal point. Northeast, southeast, southwest, or northwest.

intercardinal rolling error. Quadrantal error of a gyro compass.

intercept. Altitude difference.

international nautical mile. The nautical mile, of 1,852 meters.

interpolation. The process of determining intermediate values between given values in accordance with some known or assumed rate or system of change.

interrupted quick flashing light. A light showing quick flashes for several seconds, followed by a period of darkness.

inverse Mercator projection. Transverse Mercator projection.

inversion. A condition of the atmosphere in which temperature increases with height.

ionosphere. That part of the earth's atmosphere composed of several layers of ionized gas, at a height of about 50 to 250 miles, which bend certain radio waves back toward the surface of the earth.

irradiation. The apparent enlargement of a bright surface against a darker background.

isobar. A line connecting points having the same atmospheric pressure reduced to a common datum.

isoclinal. A line connecting points of equal magnetic dip.

isoclinal chart. A chart showing isoclinals.

isogonic. A line connecting points of equal magnetic variation.

isogonic chart. A chart showing isogonics.

isogriv. A line connecting points of equal grid variation.

isogriv chart. A chart showing isogrivs.

isomagnetic. A line connecting points of equality in some magnetic element.

isomagnetic chart. A chart showing isomagnetics.

isopor. A line connecting points of equal rate of change of any magnetic element.

isoporic chart. A chart showing isopors.

isotherm. A line connecting points of equal temperature.

junction buoy. A buoy marking the junction of two channels or two parts of a channel, when proceeding from seaward.

K-band. A radio-frequency band of 10,900 to 36,000 megacycles.

Kelvin temperature. Temperature based upon a scale starting at absolute zero (−273°15 C) and using Celsius degrees.

kilocycle. One thousand cycles.

kilometer. One thousand meters (about 0.54 nautical mile).

knot. A unit of speed equal to one nautical mile per hour.

Lambert conformal projection. A conformal conic map projection in which the surface of a sphere or spheroid, such as the earth, is conceived as developed on a cone which intersects the sphere or spheroid at two standard parallels.

land effect. Coastal refraction.

landfall. The first sighting of land when approached from seaward.

land ice. All ice formed on land.

landmark. A conspicuous object on land, serving as an indicator for guidance or warning.

land mile. Statute mile.

land navigation. Navigation across the surface of land or ice.

lane. **1.** An established route. **2.** One of the sections of the coverage area for a phase comparison system, such as Decca, in which every phase relationship may be measured.

lapse rate. The rate of decrease of temperature in the atmosphere with height.

large scale. A scale involving a relatively small reduction in size.

latitude. Angular distance north or south of the equator; the arc of a meridian between the equator and a point on the surface of the earth, measured northward or southward from the equator through 90°, and labeled N or S to indicate the direction of measurement.

latitude factor. The change in latitude along a celestial line of position for a 1′ change in longitude.

latitude line. A line of position extending in a generally east-west direction.

lattice. A pattern formed by two or more families of intersecting lines, such as loran lines of two or more rates of overlapping coverage.

L-band. A radio-frequency band of 390 to 1,550 megacycles.

lead (lĕd). A weight attached to a line.

lead (lēd). A long, narrow, navigable passage through pack ice, between rocks or shoals, etc.

leader cable. A cable carrying an electric current, signals from or the magnetic influence of which indicate the path to be followed by a craft equipped with suitable instruments.

leading light(s). A light or lights arranged to indicate the path to be followed.

lead line. The line attached to a sounding lead.

lee. That side toward which the wind blows.

leeway. The leeward motion of a vessel, due to wind, expressed as distance, speed, or an angle.

leg. One part of a track, consisting of a single course line.

legend. A title or explanation on a chart, diagram, illustration, etc.

lesser ebb. The weaker of two ebb currents occurring during a tidal day.

lesser flood. The weaker of two flood currents occurring during a tidal day.

light. A lighted aid to navigation, or its luminous energy.

lighthouse. A distinctive structure exhibiting a major navigational light.

light list. A publication tabulating navigational lights and related information.

light sector. A sector in which a navigational light is visible or has a distinctive color.

lightship. A distinctively marked vessel anchored or moored at a charted point, to serve as an aid to navigation. It has a characteristic light or lights, and usually other aids.

light vessel. Lightship.

limb. **1.** The graduated curved part of an instrument for measuring angles. **2.** The circular outer edge of a celestial body, particularly with respect to the top (upper limb) or bottom (lower limb).

line of position. A line on some point of which a vessel may be presumed to be located, as a result of observation or measurement.

line of soundings. A series of soundings obtained by a vessel underway, usually at regular intervals.

liquid compass. A compass having a bowl completely filled with liquid in which the compass card is mounted.

local apparent noon. The instant at which the apparent (true) sun is over the upper branch of the local meridian.

local apparent time. The arc of the celestial equator, or the angle at the celestial pole, between the lower branch of the local celestial meridian and the hour circle of the apparent (true) sun, measured westward from the lower branch of the local celestial meridian through 24 hours; local hour angle of the apparent (true) sun, expressed in time units, plus 12 hours.

local attraction. Local magnetic disturbance.

local civil time. Local mean time.

local hour angle. Angular distance west of the local celestial meridian; the arc of the celestial equator, or the angle at the celestial pole, between the upper branch of the local celestial meridian and the hour circle of a point on the celestial sphere, measured westward from the local celestial meridian through 360°.

local magnetic disturbance. An anomaly of the magnetic field of the earth, extending over a relatively small area, due to local magnetic influences.

local mean time. The arc of the celestial equator, or the angle at the celestial pole, between the lower branch of the local celestial meridian and the hour circle of the mean sun, measured westward from the lower branch of the local celestial meridian through 24 hours; local hour angle of the mean sun, expressed in time units, plus 12 hours.

local meridian. The meridian through any particular place or observer.

local sidereal time. The arc of the celestial equator, or the angle at the celestial pole, between the upper branch of the local celestial meridian and the hour circle of the vernal equinox, measured westward from the upper branch of the local celestial meridian through 24 hours; local hour angle of the vernal equinox, expressed in time units.

log. **1.** An instrument for measuring the speed or distance, or both, traveled by a vessel. **2.** Deck log.

long-distance navigation. **1.** Navigation requiring only aids usable at long range, relatively few of which could provide world coverage. **2.** Navigation on a long trip, as a voyage across an ocean.

longitude. Angular distance east or west of the prime meridian; the arc of a parallel, or the angle at the pole, between the prime meridian and the meridian of a point on the earth, measured eastward or westward from the prime meridian through 180°, and labeled E or W to indicate the direction of measurement.

longitude factor. The change in longitude along a celestial line of position for a 1′ change in latitude.

longitude line. A line of position extending in a generally north-south direction.

long-range navigation. Long-distance navigation, definition 1.

loom. The glow of a light which is below the horizon, caused by reflection by solid particles in the air.

loran. An electronic navigational system by which hyperbolic lines of position are determined by measuring the difference in the time of reception of synchronized pulse signals.

loran rate. The frequency channel and pulse repetition rate by which a pair of loran stations is identified.

loran tables. Publications containing tabular data for plotting loran lines of position.

lower branch. That half of a meridian or celestial meridian from pole to pole which passes through the antipode or nadir of a place.

lower high water. The lower of two high tides occurring during a tidal day.

lower limb. That half of the limb (of a celestial body) having the lesser altitude.

lower low water. The lower of two low tides occurring during a tidal day.

lower transit. Transit across the lower branch of the celestial meridian.

low frequency. Radio frequency of 30 to 300 kilocycles per second.

low tide. The minimum height reached by a falling tide.

low water. Low tide.

low water inequality. The difference between the heights of the two low tides during a tidal day.

low water lunitidal interval. The interval of time between the transit (upper or lower) of the moon and the next low water at a place.

loxodrome. Rhumb line.

lubber's line. A reference line on any direction-indicating instrument, marking the reading which coincides with the heading.

luminous range. The extreme distance at which a light can be seen when limited only by the intensity of the light, clearness of the atmosphere, and sensitiveness of the observer's eyes.

lunar tide. That part of the tide due solely to the tide-producing force of the moon.

lunitidal interval. The interval of time between the transit (upper or lower) of the moon and the next high water or low water at a place.

magnetic amplitude. Amplitude relative to magnetic east or west.

magnetic azimuth. Azimuth relative to magnetic north.

magnetic bearing. Bearing relative to magnetic north.

magnetic chart. A chart showing magnetic information.

magnetic compass. A compass depending for its directive force upon the attraction of the magnetism of the earth for a magnet free to turn in any horizontal direction.

magnetic compass table. Deviation table.

magnetic course. Course relative to magnetic north.

magnetic declination. Variation.

magnetic dip. The angle between the horizontal and lines of force of the earth's magnetic field.

magnetic equator. That line on the surface of the earth connecting all points at which the magnetic dip is zero.

magnetic field. The space in which a magnetic influence exists.

magnetic heading. Heading relative to magnetic north.

magnetic latitude. The angle having a tangent equal to half that of the magnetic dip at the place.

magnetic lines of force. Closed lines indicating by their direction the direction of magnetic influence.

magnetic meridian. A line of horizontal magnetic force of the earth.

magnetic north. The direction north as indicated by the earth's magnetic lines of force.

magnetic pole. Either of the two places on the surface of the earth where the magnetic dip is 90°.

magnetic storm. Violent, prolonged disturbance of the magnetic characteristics of the earth.

magnetic track. The direction of the track relative to magnetic north.

magnetic variation. Variation.

magnitude. Relative brightness of a celestial body.

maneuvering board. A polar coordinate plotting sheet devised to facilitate solution of problems involving relative movement.

manual radio direction finder. A radio direction finder which requires manual operation.

map. A representation, usually on a plane surface, of all or part of the surface of the earth, celestial sphere, or other area; showing relative size and position, according to a given projection, of the various features represented.

map projection. A representation or method of representing all or part of the surface of a sphere or spheroid, such as the earth, upon a plane surface.

March equinox. Vernal equinox.

marine navigation. The navigation of water craft.

marine sextant. A sextant designed primarily for marine navigation.

master compass. That part of a remote-indicating compass system which determines direction for transmission to various repeaters.

master station. The governing station of two or more synchronized transmitting stations.

maximum ebb. The greatest speed of an ebb current.

maximum flood. The greatest speed of a flood current.

mean sea level. The average height of the surface of the sea for all stages of the tide, usually determined from hourly readings.

mean sun. A fictitious sun conceived to move eastward along the celestial equator at a uniform rate equal to the average rate of the apparent sun along the ecliptic.

mean tide level. Half-tide level.

mean time. Time based upon rotation of the earth relative to the mean sun.

measured mile. A length of one nautical mile, the limits of which have been accurately measured and are indicated by ranges ashore.

medium frequency. Radio frequency of 300 to 3,000 kilocycles per second.

megacycle. One million cycles.

Mercator projection. A conformal cylindrical map projection in which the surface of a sphere or spheroid, such as the earth, is conceived as developed on a cylinder tangent along the equator, with the expansion of the meridians being equal to that of the parallels.

Mercator sailing. A method of solving the various problems involving course, distance, difference of latitude, difference of longitude, and departure by considering them in the relation in which they are plotted on a Mercator chart.

mercurial barometer. An instrument which determines atmospheric pressure by measuring the height of a column of mercury which the atmosphere will support.

meridian. A great circle through the geographical poles of the earth or a similar body.

meridian altitude. The altitude of a celestial body when it is on the celestial meridian.

meridian angle. Angular distance east or west of the local celestial meridian; the arc of the celestial equator, or the angle at the celestial pole, between the upper branch of the local celestial meridian and the hour circle of a point on the celestial sphere, measured eastward or westward from the local celestial meridian through 180°, and labeled E or W to indicate the direction of measurement.

meridian observation. Measurement of meridian altitude, or the altitude so measured.

meridian passage. Meridian transit.

meridian sailing. Following a true course of 000° or 180°.

meridian transit. The passage of a celestial body across a celestial meridian.

meridional difference. The difference between the meridional parts of any two given parallels.

meridional parts. The length of the arc of a meridian between the equator and a given parallel on a Mercator chart, expressed in units of 1′ of longitude at the equator.

meteorological tide. A change in water level due to meteorological conditions.

meteorology. The science of the atmosphere.

micrometer drum. A cylinder having a vernier for precise measurement, as on certain type sextants.

micrometer drum sextant. A marine sextant providing a precise reading by means of a micrometer drum attached to the index arm, and having an endless tangent screw for controlling the position of the index arm.

microsecond. One-millionth of a second.

microwave. A very short radio wave, usually one shorter than one meter.

middle ground. A shoal with channels on both sides.

middle latitude. Half the arithmetical sum of the latitudes of two places on the same side of the equator.

middle-latitude sailing. A method of converting departure into difference of longitude, or vice versa, when the course is not 090° or 270°, by assuming that such a course is steered at the middle latitude.

mid latitude. Middle latitude.

millibar. A unit of pressure equal to 1,000 dynes per square centimeter.

millisecond. One-thousandth of a second.

mist. Thin fog of relatively large particles, or very fine rain.

mixed current. A type of tidal current characterized by a conspicuous difference in speed between the two flood currents or two ebb currents usually occurring each tidal day.

mixed tide. A type of tide having a large inequality in the heights of either the two high tides or the two low tides usually occurring each tidal day.

modified Lambert conformal projection. A modification of the Lambert conformal projection for use in polar regions, the higher standard parallel being almost at the pole, and the parallels being expanded slightly to form complete concentric circles.

modulation. Variation of some characteristic of a wave, called the carrier wave, in accordance with instantaneous values of another wave, called the modulating wave.

most probable position. That position of a craft judged to be most accurate when the exact position is not known.

Mumetal. The trade name for an alloy of nickel and iron used for temporary magnets.

nadir. That point on the celestial sphere vertically below the observer, or 180° from the zenith.

name. The label of a numerical value, particularly the N (north) or S (south) label of latitude and declination.

natural scale. The ratio between the linear dimensions of a chart, drawing, etc., and the actual dimensions represented, expressed as a proportion.

nautical almanac. A periodical publication of astronomical data designed primarily for marine navigation.

nautical astronomy. Navigational astronomy.

nautical chart. A chart intended primarily for marine navigation.

nautical mile. A unit of distance equal to 1,852 meters (6,076.11549 U. S. feet, approximately). This is equal approximately to the length of 1′ of latitude.

nautical twilight. The period of incomplete darkness when the upper limb of the sun is below the visible horizon, and the center of the sun is not more than 12° below the celestial horizon.

naveam. An urgent notice of dangers to navigation in Eastern Atlantic or Mediterranean waters.

navigable semicircle. That half of a cyclonic storm area to the *left* of the storm track in the northern hemisphere, and to the *right* of the storm track in the southern hemisphere. In this semicircle the winds are weaker and tend to blow a vessel away from the path of the storm.

navigation. The process of directing the movement of a craft from one point to another.

navigational aid. An instrument, device, chart, method, etc., intended to assist in the navigation of a craft.

navigational astronomy. That part of astronomy of direct use to a navigator, comprising principally celestial coordinates, time, and the apparent motions of celestial bodies.

navigational planets. The four planets commonly observed in celestial navigation; Venus, Mars, Jupiter, and Saturn.

navigational triangle. The spherical triangle solved in computing altitude and azimuth and great-circle sailing problems.

neap tides. The tides occurring near the times of first and last quarter of the moon, when the range of tide tends to decrease.

Ney's projection. Modified Lambert conformal projection.

night effect. A radio bearing error occurring chiefly at night.

nightmark. An object of distinctive characteristics serving as an aid to navigation during darkness.

night order book. A notebook in which the commanding officer of a vessel writes, as a guide to deck watch officers, various memoranda and orders relating to the navigation of the vessel during the night.

nimbostratus. A dark, low, shapeless cloud layer (mean upper level below 6,500 ft.) usually nearly uniform; the typical rain cloud.

nimbus. A characteristic rain cloud.

noise. Random interference which appears as extraneous signals in radio receivers or on the scope of electronic instruments.

noon constant. A predetermined value added to a meridian or ex-meridian sextant altitude to determine the latitude.

noon sight. Measurement of the altitude of the sun at local apparent noon, or the altitude so measured.

northing. The distance a craft makes good to the north.

north-upward plan position indicator. A plan position indicator with north at the top of the indicator regardless of heading.

null. Minimum or zero signal.

nun buoy. A buoy the above water part of which is in the shape of a cone or a truncated cone.

nutation. Irregularities in the precessional motion of the equinoxes.

oblique Mercator projection. A conformal cylindrical map projection in which points on the surface of a sphere or spheroid, such as the earth, are conceived as developed by Mercator principles on a cylinder tangent along an oblique great circle.

observed altitude. Corrected sextant altitude.

observed latitude. Latitude determined by means of an observation.

observed longitude. Longitude determined by means of an observation.

occluded front. The front formed when a cold front overtakes a warm front.

occulting light. A light totally eclipsed at intervals, the duration of light being equal to or greater than that of darkness.

oceanography. The application of the sciences to the phenomena of the oceans.

ocean station vessel. A ship which remains close to an assigned position at sea to take weather observations, assist aircraft, etc.

oersted. The centimeter-gram-second electromagnetic unit of magnetic intensity.

offshore. Away from the shore.

off soundings. In an area where the depth of water cannot be measured by an ordinary sounding lead, generally considered to be beyond the 100-fathom line.

omnidirectional. In all directions.

on soundings. In an area where the depth of water can be measured by an ordinary sounding lead, generally considered to be within the 100-fathom line.

on the beam. Bearing approximately 090° relative ("on the starboard beam") or 270° relative ("on the port beam").

on the bow. Bearing approximately 045° relative ("on the starboard bow") or 315° relative ("on the port bow").

on the quarter. Bearing approximately 135° relative ("on the starboard quarter") or 225° relative ("on the port quarter").

opposition. The situation of two celestial bodies having either celestial longitudes or sidereal hour angles differing by 180°.

ordinate. The vertical coordinate of a set of rectangular coordinates.

orthographic projection. A perspective azimuthal projection in which the projecting lines, emanating from a point at infinity, are perpendicular to a tangent plane.

orthomorphic projection. A projection in which very small shapes are correctly represented.

overfalls. Short, breaking waves occurring when a current passes over a shoal or other submarine obstruction or meets a contrary current or wind.

pack. A large field of floating pieces of sea ice which have drifted together.

parallactic angle. That angle of the navigational triangle at the celestial body.

parallax. The difference in the apparent direction or position of an object when viewed from different points.

parallax in altitude. Geocentric parallax of a celestial body at any given altitude.

parallel. A circle on the surface of the earth, or a similar body, parallel to the plane of the equator and connecting all points of equal latitude, or a closed curve resembling or approximating such a circle.

parallel of altitude. A circle of the celestial sphere parallel to the horizon, connecting all points of equal altitude.

parallel of declination. A circle of the celestial sphere parallel to the celestial equator.

parallel of latitude. 1. Parallel. **2.** A circle of the celestial sphere, parallel to the ecliptic, and connecting points of equal celestial latitude.

parallel rulers. An instrument for transferring a line parallel to itself.

parallel sailing. A method of converting departure into difference of longitude, or vice versa, when the true course is 090° or 270°.

patent log. Any mechanical log, particularly a taffrail log.

P-band. A radio-frequency band of 225 to 390 megacycles.

pelorus. A dumb compass, or a compass card without a directive element, suitably mounted to provide means for measuring bearings.

per gyro compass. Relating to the gyro compass.

perigean tides. Tides of increased range occurring when the moon is near perigee.

perigee. That orbital point nearest the earth when the earth is the center of attraction (as in the case of the moon).

perihelion. That orbital point nearest the sun when the sun is the center of attraction (as in the case of a planet).

Permalloy. The trade name for an alloy of nickel and iron, which is easily magnetized and demagnetized.

permanent magnetism. Magnetism which is retained for long periods without appreciable reduction, unless the magnet is subjected to a demagnetizing force.

personal error. A systematic error in observations due to the characteristics of the observer.

perspective projection. The representation of a figure on a surface by means of projecting lines emanating from a single point.

per standard compass. Relating to the standard magnetic compass.

per steering compass. Relating to the magnetic steering compass.

phase correction. That correction to sextant altitude due to offset of the apparent center of a body because of its phase.

photogrammetry. The art or science of surveying by photography.

pilot chart. A chart giving information on ocean currents, weather, and other items of interest to a navigator.

piloting. Navigation involving frequent or continuous determination of position or a line of position relative to geographical points, to a high order of accuracy.

pilot station. The place where the services of a pilot may be obtained.

pilot waters. 1. Areas in which the services of a pilot are desirable. **2.** Waters in which navigation is by piloting.

Pitot tube. A tube with an open end pointed toward a moving stream of fluid. It is usually associated with a coaxial or nearly parallel tube having holes in its side to permit measurement of static pressure.

plane sailing. A method of solving the various problems involving course, distance, difference of latitude, and departure, in which the earth or a small part of it is considered a plane.

plan position indicator. A radar scope which provides a maplike presentation of the surrounding area.

plot. A drawing consisting of lines and points graphically representing certain conditions, as the progress of a craft.

plotter. An instrument for plotting lines and measuring angles on a chart or plotting sheet.

plotting chart. A chart designed primarily for plotting dead reckoning, lines of position from celestial observations, or radio aids, etc.

plotting sheet. A blank chart showing only the graticule and one or more compass roses, so that the plotting sheet can be used for any longitude.

point of arrival. The position a craft is assumed to have reached or will reach after following specified courses for specified distances from a specified point.

point of departure. The point from which the initial course to reach the destination begins.

point of destination. The point at which the final course from the point of departure ends, exclusive of the courses needed to reach a berth.

polar distance. Angular distance from a celestial pole, usually the elevated pole.

Polaris correction. A correction to be applied to the observed altitude of Polaris to obtain the latitude.

polarization error. That radio bearing error due to horizontally polarized components of the electric field under certain transmission conditions.

polar navigation. Navigation in polar regions.

polar projection. A map projection centered on a pole.

pole. **1.** Either of the two points of intersection of the surface of the earth or similar body and its axis. **2.** A magnetic pole.

polyconic projection. A conic map projection in which the surface of a sphere or spheroid, such as the earth, is conceived as developed on a series of tangent cones, which are then spread out to form a plane.

position. A point defined by stated or implied coordinates, particularly one on the surface of the earth.

position angle. Parallactic angle.

post meridian. After noon.

precession. Change in the direction of the axis of rotation of a spinning body, as a gyroscope, when acted upon by a torque.

precession of the equinoxes. The conical motion of the earth's axis about the vertical to the plane of the ecliptic, caused by the attractive force of the sun, moon, and other planets on the equatorial protuberance of the earth. It produces a slow change in declination and sidereal hour angle of stars.

precomputed altitude. The altitude of a celestial body computed before observation, and with the sextant altitude corrections applied with reversed sign.

pressure ice. Sea ice having any readily observed roughness of the surface.

primary radar. Radar using only reflection for indication of targets.

primary tide station. A place at which continuous tide observations are made over a number of years to obtain basic tidal data for the locality.

prime meridian. The meridian of longitude 0°, used as the origin for the measurement of longitude.

prime vertical. Prime vertical circle.

prime vertical circle. That vertical circle through the east and west points of the horizon.

principal vertical circle. That vertical circle through the north and south points of the horizon, coinciding with the celestial meridian.

prismatic error. That error due to lack of parallelism of the two faces of an optical element, such as a mirror or a shade glass.

profile. A graph showing elevation or distribution of some property along a line; as the graphic record made by a recording echo sounder while a vessel is underway.

proper motion. That component of the space motion of a celestial body perpendicular to the line of sight, resulting in the change of a star's apparent position relative to other stars.

proportional parts. Numbers in the same proportion as a set of given numbers, used as an aid to interpolation.

protractor. An instrument for measuring angles on a surface; an angular scale.

psychrometer. An instrument consisting of suitably mounted dry-bulb and wet-bulb thermometers for determining relative humidity and dew point.

pulse. A very short burst of electromagnetic energy.

pulse duration. The time interval during which the amplitude of a pulse is at or greater than a specified fraction of the maximum value.

pulse interval. The time interval between corresponding parts of successive pulses in a sequence characterized by uniform spacing.

pulse length. Pulse duration.

pulse modulation. The process of forming very short bursts of a carrier wave, separated by relatively long periods during which no carrier wave is transmitted.

pulse recurrence rate. Pulse repetition rate.

pulse repetition rate. The rate at which recurrent pulses are transmitted, usually expressed in pulses per second.

pulse separation. The time interval between the trailing edge of one pulse and the leading edge of the next pulse.

pulse train. A group of related pulses, constituting a series.

pulse width. Pulse duration.

pumping. Unsteadiness in the height of the mercury column of a barometer.

Q-band. A radio-frequency band of 36,000 to 46,000 megacycles.

quadrant. An instrument similar to a sextant but having a range of 180°. Usually called a "sextant."

quadrantal correctors. Masses of soft iron placed near a magnetic compass to correct for quadrantal deviation.

quadrantal deviation. Deviation which changes its sign (E or W) approximately each 90° change of heading.

quadrantal error. An error which changes sign (plus or minus) each 90°.

quadrantal spheres. Spherical quadrantal correctors.

quick flashing light. A light showing short flashes at the rate of not less than 60 per minute.

quintant. An instrument similar to a sextant but having a range of 144°. Usually called a "sextant."

race. A rapid current or a constricted channel in which such a current flows.

racon. A nondirectional radar beacon which returns a coded signal when triggered by a radar signal.

radar. A system of determining distance of an object by measuring the time interval between transmission of a pulse signal and reception of a signal returned as an echo or by a transmitter triggered by the outgoing signal. The bearing of the object can be determined by noting the orientation of the directional antenna.

radar beacon. A radiobeacon transmitting a characteristic signal on radar frequency, permitting a craft to determine the bearing and with some types the distance of the beacon.

radar bearing. A bearing obtained by radar.

radar conspicuous object. An object which returns a strong radar echo.

radar horizon. The radio horizon of a radar antenna.

radar reflector. A device capable of or intended for reflecting radar signals.

radar shadow. A condition in which radar signals do not reach a region because of an intervening obstruction.

radar target. An object which reflects a sufficient amount of a radar signal to produce an echo signal on the radar screen.

radian. The angle subtended at the center of a circle by an arc equal in length to a radius of the circle. It is equal to $180° \div \pi$, or approximately $57°17'44''.8$.

radiant energy. Energy transmitted by radiation, as sound, heat, light, etc.

radiation. The emission, transmission, and absorption of radiant energy by emanation through space.

radio. Communication by electromagnetic waves, without a connecting wire.

radio acoustic ranging. Determining distance by a combination of radio and sound, the radio being used to indicate the instant of transmission or reception of the sound, and distance being determined by the time of transit of sound, usually in water.

radio aid to navigation. An aid to navigation transmitting information by radio waves.

radio astronomy. The science which deals with radio and thermal radiation from extraterrestrial sources.

radiobeacon. A radio transmitter emitting a characteristic signal to permit a craft with suitable equipment to determine its direction, distance, or position relative to the beacon.

radio bearing. The bearing of a radio transmitter from a receiver, as determined by a radio direction finder.

radio compass. Obsolete expression for radio direction finder.

radio direction finder. Radio receiving equipment which determines the direction of arrival of a signal by measuring the orientation of the wave front, using a loop antenna.

radio direction finder station. A radio station provided with equipment for obtaining radio bearings, particularly such a station on the shore.

radio frequency. Any frequency at which electromagnetic radiation of energy is useful for communication.

radio horizon. The line at which direct rays from a transmitting antenna become tangent to the earth's surface.

radio navigation. Navigation by means of radio.

radio range. A radio station providing course guidance, or the courses so provided.

radiosonde. An instrument carried aloft by a free, unmanned balloon and equipped with elements for determining temperature, pressure, and relative humidity and automatically transmitting the measurements by radio.

radio time signal. A time signal sent by radio.

radio waves. Waves produced by oscillation of an electric charge at a frequency useful for radio communication.

radius of visibility. The radius of a circle limiting the area in which an objective can be seen under specified conditions.

radome. A radio-transparent housing for a radar antenna assembly.

ramark. A radar beacon which continuously transmits a signal appearing as a radial line on the PPI, the line indicating the direction of the beacon.

random error. A chance error, unpredictable in magnitude or sign.

range. **1.** Two or more objects in line. **2.** Distance in a single direction or along a great circle. **3.** The extreme distance at which an object or light can be seen, or a radio signal can be used. **4.** A radio station providing course guidance, or the courses so provided. **5.** A predetermined line along which a craft moves while certain data are recorded, or the station at which this takes place.

range finder. An optical instrument for measuring the distance to an object.

range lights. Two or more lights in the same horizontal direction, particularly those lights so placed as navigational aids to mark any line of importance to vessels, as a channel.

range of tide. The difference in height between consecutive high and low tides at a place.

range of visibility. The extreme distance at which an object or light can be seen.

Rankine temperature. Temperature based upon a scale starting at absolute zero (−459°67 F) and using Fahrenheit degrees.

rational horizon. Celestial horizon.

ratio of ranges. The ratio of the ranges of tide at two places.

ratio of rise. The ratio of the height of tide at two places.

Réaumur temperature. Temperature based upon a scale in which, under standard atmospheric pressure, water freezes at 0° and boils at 80° above zero.

rectangular projection. A cylindrical map projection with uniform spacing of the parallels.

rectified altitude. Sextant altitude corrected for inaccuracies in the reading (instrument, index, and personal errors, as applicable) and inaccuracies in the reference level (principally dip or Coriolis), but not for other errors. This is the altitude a celestial body appears to be above the celestial horizon, the value measured at an observatory, and for this reason is called "apparent altitude" by astronomers.

red azimuth tables. H.O. Pub. No. 260, *Azimuths of the Sun.*

red magnetism. The magnetism of the north-seeking end of a freely suspended magnet.

red sector. A sector of the circle of visibility of a navigational light in which a red light is exhibited.

reduction. The process of substituting for an observed value one derived therefrom.

reduction to the meridian. The process of applying a correction to an altitude observed when a celestial body is near the celestial meridian, to find the equivalent meridian altitude.

reference station. A place for which independent daily predictions are given in the tide or tidal current tables, from which corresponding predictions are obtained for other stations by means of differences or factors.

refraction. The change in direction of motion of a ray of radiant energy as it passes obliquely from one medium into another in which the speed of propagation is different.

relative azimuth. Azimuth relative to heading.

relative bearing. Bearing relative to heading or to the craft.

relative humidity. The percentage of saturation of the air.

relative movement. Motion of one object or body relative to another.

relief. Inequalities in the elevations of the terrain, or their representation on a chart.

remote-indicating compass. A compass equipped with one or more indicators to repeat at a distance the readings of the master compass.

repeater. A device for repeating at a distance the indications of an instrument or device.

residual deviation. Deviation of a magnetic compass after adjustment or compensation.

resolution. The separation, by a radar or optical system, of parts of an object or of two or more objects close together, or the degree of ability to make such a separation.

retired line of position. A line of position which has been moved backward to correspond with a time previous to that for which the line was established.

retrace. The path of the visible dot from the end of one sweep to the start of the next sweep across the face of a cathode ray tube.

retrograde motion. The apparent motion of a planet westward among the stars.

rhumb bearing. The direction of a rhumb line through two terrestrial points.

rhumb course. The direction of the rhumb line from the point of departure to the destination.

rhumb line. A line on the surface of the earth making the same oblique angle with all meridians.

rhumb line distance. Distance along a rhumb line.

right ascension. Angular distance east of the vernal equinox; the arc of the celestial equator, or the angle at the celestial pole, between the hour circle of the vernal equinox and the hour circle of a point on the celestial sphere, measured eastward from the hour circle of the vernal equinox through 24^h.

rise of tide. Vertical distance from the chart datum to a high water datum, such as mean high water.

rocking the sextant. Swinging the arc.

rotary current. A tidal current which changes direction progressively through 360° during a tidal-day cycle, without coming to slack water.

round of sights. A group of sights made over a short period of time.

running fix. A position determined by crossing lines of position with an appreciable time difference between them and advanced or retired to a common time.

sailing. A method of solving the various problems involving course, distance, difference of latitude, difference of longitude, and departure.

sailing chart. A small-scale nautical chart for offshore navigation.

sailing directions. A descriptive book for the use of mariners, containing detailed information of coastal waters, harbor facilities, etc., of an area, particularly along coasts other than those of the United States.

St.-Hilaire method. The establishing of a line of position from the observation of the altitude of a celestial body by the use of an altitude difference and azimuth.

same name. A name (such as north or south) the same as that of something else. Usually used in connection with declination and latitude.

S-band. A radio-frequency band of 1,550 to 5,200 megacycles.

scalar. A quantity having magnitude only.

scale. **1.** A series of marks or graduations at definite intervals. **2.** The ratio between the linear dimensions of a chart, map, drawing, etc., and the actual dimensions represented.

scope. The face of a cathode ray tube.

sea-air temperature difference correction. That sextant altitude correction resulting from abnormal refraction occurring when there is a difference in the temperature of the water and air at the surface.

sea anchor. An object towed by a vessel to keep it end-on to a heavy sea or surf or to reduce the drift.

sea buoy. The outermost buoy marking the entrance to a channel or harbor.

sea ice. Ice formed by the freezing of sea water.

sea level. The height of the surface of the sea.

seamark. A conspicuous object in the water, serving as an indicator for guidance or warning of a craft.

sea mile. Nautical mile.

seamount. An elevation of relatively small horizontal extent rising from the bottom of the sea.

sea return. Radar echoes reflected from the sea.

sea room. Space in which to maneuver without grounding or colliding.

sea tilt correction. That altitude correction due to tilting of the surface of the sea.

seaway. A moderately rough sea.

secondary radar. Radar using automatic retransmission when triggered by a radar signal.

secondary tide station. A place at which tide observations are made over a short period to obtain data for a specific purpose.

sector. Part of a circle bounded by two radii and an arc.

sectored light. A light having sectors of different colors or the same color in specific sectors separated by dark sectors.

secular. Of or pertaining to a long period of time.

seismic sea wave. One of a series of ocean waves propagated outward from the epicenter of a submarine earthquake.

semicircular deviation. Deviation which changes sign (E or W) approximately each 180° change of heading.

semidiurnal. Having a period of, occurring in, or related to approximately half a day.

semidiurnal current. Tidal current having two flood currents and two ebb currents each tidal day.

semidiurnal tide. Tide having two high tides and two low tides each tidal day.

sense. The general direction from which a radio signal arrives.

sense antenna. An antenna used to resolve a 180° ambiguity in a directional antenna.

sensible horizon. That circle of the celestial sphere formed by the intersection of the celestial sphere and a plane through the eye of the observer and perpendicular to the zenith-nadir line.

set. The direction toward which a current flows.

seven-eighths rule. A rule of thumb which states that the approximate distance to an object broad on the beam equals ⅞ of the distance traveled while the relative bearing (right or left) changes from 30° to 60° or from 120° to 150°.

seven-tenths rule. A rule of thumb which states that the approximate distance to an object broad on the beam equals 7/10 of the distance traveled while the relative bearing (right or left) changes from 22°.5 to 45° or from 135° to 157°.5.

seven-thirds rule. A rule of thumb which states that the approximate distance to an object broad on the beam equals 7/3 of the distance traveled while the relative bearing (right or left) changes from 22°.5 to 26°.5, 67°.5 to 90°, 90° to 112°.5, or 153°.5 to 157°.5.

sextant. A double-reflecting instrument for measuring angles, primarily altitudes of celestial bodies. Originally, the term was applied only to such instruments having an arc of 60°, but the term is now generally applied to all such instruments regardless of the length of arc.

sextant adjustment. The process of checking the accuracy of a sextant and removing or reducing its error.

sextant altitude. Altitude as indicated by sextant, before corrections are applied.

sextant altitude correction. Any of several corrections applied to a sextant altitude in the process of converting it to observed altitude.

sextant error. The error in the reading of a sextant, due either to lack of proper adjustment or imperfection of manufacture.

shade. Shade glass.

shade error. That error of an optical instrument due to refraction in the shade glasses.

shade glass. A darkened transparency that can be moved into the line of sight of an optical instrument, such as a sextant, to reduce the intensity of light reaching the eye.

shielding factor. The ratio of the strength of the magnetic field at a compass to the strength if there were no disturbing material nearby.

ship heading marker. A mark indicating the position or direction of the ship's head.

ship's head. Heading of a vessel.

shoran. A precision electronic position fixing system using a pulse transmitter and receiver and two transponder beacons at fixed points.

short-distance navigation. **1.** Navigation employing aids usable at short ranges only. **2.** Navigation on a short trip.

short-long flashing light. A light showing a short flash of about 0.4 second, and a long flash of four times that duration, this combination recurring about six to eight times per minute.

short-range navigation. Short-distance navigation, definition 1.

side error. That error in the reading of a marine sextant due to nonperpendicularity of the horizon glass to the frame.

sidereal. Of or pertaining to the stars.

sidereal day. The duration of one rotation of the earth on its axis, with respect to the vernal equinox.

sidereal hour angle. Angular distance west of the vernal equinox; the arc of the celestial equator, or the angle at the celestial pole, between the hour circle of the vernal equinox and the hour circle of a point on the celestial sphere, measured westward from the hour circle of the vernal equinox through 360°.

sidereal time. Time based upon the rotation of the earth relative to the vernal equinox.

sight. Observation of the altitude, and sometimes also the azimuth, of a celestial body for a line of position; or the data obtained by such an observation.

sight reduction. The process of deriving from a sight the information needed for establishing a line of position.

sight reduction tables. Tables for performing sight reduction, particularly those for determining computed altitude.

signal-to-noise ratio. The ratio of the amplitude of a desired radio signal at any point to the amplitude of noise at the same point.

signature. The graphic record of the magnetic properties of a vessel traced as the vessel passes over a recording instrument.

skip distance. The least distance from a transmitting antenna at which a sky wave can normally be received.

skip zone. The area between the outer limit of reception of ground waves and the inner limit of reception of sky waves, where no signal is received.

sky compass. An instrument for determining azimuth of the sun by utilizing the polarization of sunlight in the sky.

sky wave. An indirect radio wave which travels from the transmitting antenna into the sky, where the ionosphere bends it back toward the earth.

sky-wave correction. A correction to be applied to the reading of the indicator of an electronic instrument when sky waves are used, to obtain the equivalent ground-wave reading.

slack water. The condition when the speed of a tidal current is zero.

slave station. A transmitting station the emissions of which are controlled by a master station.

small circle. The intersection of a sphere and a plane which does not pass through its center.

small scale. A scale involving a relatively large reduction in size.

smog. A mixture of smoke and fog.

sofar. A navigational system by which hyperbolic lines of position are determined by measuring, at shore listening stations, the difference in the time of reception of sound signals produced in a sound channel in the sea, under the vessel.

soft iron. Iron or steel which is easily magnetized by induction, but loses its magnetism when the magnetic field is removed.

solar day. The duration of one rotation of the earth on its axis, with respect to the sun.

solar tide. That part of the tide due solely to the tide-producing force of the sun.

solar time. Time based upon the rotation of the earth relative to the sun.

solstice. One of the two points of the ecliptic farthest from the celestial equator, or the instant the sun occupies one of these points, when its declination is maximum.

solstitial tides. Tides occurring near the times of the solstices, when the tropic range is especially large.

sonar. A system of determining distance of an underwater object by measuring the interval of time between transmission of an underwater sonic or ultrasonic signal and return of its echo.

sonic depth finder. An echo sounder operating in the audible range of signals.

sonic navigation. Navigation by means of sound waves whether or not they are within the audible range.

sonne. A German forerunner of the British consol.

sonobuoy. A buoy with equipment for automatically transmitting a radio signal when triggered by an underwater sound signal.

sound buoy. A buoy equipped with a characteristic sound signal.

sounding. Measured or charted depth of water, or the measurement of such depth.

sounding lead (lĕd). A lead used for determining depth of water.

sounding line. The line attached to a sounding lead.

sounding machine. An instrument for measuring depth of water by lowering a recording device.

sounding wire. The wire attached to the recording device of a sounding machine.

sound wave. An audible disturbance in any material medium or, by extension, a similar disturbance outside the audible range.

southing. The distance a craft makes good to the south.

space motion. Motion of a celestial body through space.

spar buoy. A buoy made of a tapered log or of metal similarly shaped.

specific pulse repetition rate. The pulse repetition rate of a pair of transmitting stations using a group of rates differing only slightly from each other.

speed error. That error introduced in a gyro compass by the north-south component of the craft's motion.

speed line. A line of position approximately perpendicular to the course.

speed of advance. The speed expected to be made good over the ground.

speed over the ground. The speed actually made good over the ground.

spherical sailing. Any of the sailings that takes into account the spherical or spheroidal shape of the earth.

spherical triangle. A closed figure having arcs of three great circles as sides.

spheroid. An ellipsoid.

spillover. The receiving of a radio signal of a frequency differing from that to which the receiver is tuned.

splitting. The dividing of a sky-wave signal into two or more peaks.

spring range. The mean semidiurnal range of tide when spring tides are occurring.

spring tides. The tides occurring near the times of full moon and new moon, when the range of tide tends to increase.

SS loran. Sky-wave synchronized loran.

stadimeter. An instrument for determining the distance to an object of known height by measuring the angle subtended at the observer by the object.

stand. The condition at high tide or low tide when there is no change in the height of the water.

standard compass. A compass designated as the standard for a vessel.

standard parallel. A parallel on a map projection, along which the scale is as stated.

standard time. A variation of zone time used on or near land, with somewhat irregular but defined zone limits.

star finder. A device to facilitate the recognition of stars.

star globe. A globe representing the celestial sphere, on which the apparent positions of the stars are indicated.

static. Radio noise caused by natural electrical discharges in the atmosphere.

station buoy. A buoy used to mark the approximate station of an important buoy or a lightship.

station error. The difference between the direction of gravity and the perpendicular (normal) to the reference spheroid representing the earth.

station pointer. Three-arm protractor.

statute mile. A unit of distance equal to 5,280 feet in the United States.

steam fog. Frost smoke.

steering compass. A compass by which a craft is steered.

steering repeater. A compass repeater by which a craft is steered.

stereographic projection. A perspective, conformal, azimuthal map projection in which points on the surface of a sphere or spheroid, such as the earth, are conceived as projected by radial lines from any point on the surface to a plane tangent to that point opposite the point of projection.

storm tide. Increased water level due to a storm.

storm wave. A high tide caused by wind.

stranding. A serious grounding.

stratocumulus. Low clouds (mean upper level below 6,500 ft.) composed of a layer or patches of globular masses or rolls.

stratus. A low cloud (mean upper level below 6,500 ft.) in a uniform layer, resembling fog but not resting on the surface.

stream current. A relatively narrow, deep, fast-moving ocean current.

strength of current. The phase of a tidal current at which the speed is a maximum, or the speed at this time.

submarine bell. A bell whose signal is transmitted through the water.

submarine navigation. **1.** Navigation of a submarine, whether or not submerged. **2.** Underwater navigation.

submarine oscillator. A large, electrically operated diaphragm horn which produces a powerful sound for transmission through water.

submarine sound signal. A sound signal transmitted through water.

subordinate station. A place for which tide or tidal current predictions are determined by applying a correction to the predictions of a reference station.

summer solstice. That point on the ecliptic occupied by the sun at maximum northerly declination, or the instant the sun occupies this position, about June 21.

Sumner line. A celestial line of position, particularly one established by the Sumner method.

Sumner method. The establishing of a celestial line of position by computing two points on the line and connecting these with a straight line.

super high frequency. Radio frequency of 3,000 to 30,000 megacycles per second.

supplement. An angle equal to 180° minus the given angle.

surface navigation. Navigation of a vessel on the surface of the earth.

surveying sextant. A sextant intended primarily for use in hydrographic surveying.

sweep. The motion of the visible dot across the face of a cathode ray tube, as a result of deflections of the electron beam.

sweeping. The process of towing a submerged line or object to locate any submerged dangers or determine the least depth of an area; or the process of clearing an area of such dangers.

swell. A relatively long wind wave, or series of waves, that have traveled a considerable distance from the generating area.

swell direction. The direction *from* which swell is moving.

swinging ship. Placing a vessel on various headings to determine deviation.

swinging the arc. The process of rotating a sextant during observation, to determine the foot of the vertical circle through the body being observed.

swirl error. The additional error in the reading of a magnetic compass during a turn, due to friction in the compass liquid.

synoptic chart. A chart showing the distribution of meteorological conditions over an area at a given time. Popularly called a "weather map."

systematic error. An error due to some law by which it might be predicted.

tabulated altitude. Altitude taken directly from a table, before interpolation.

taffrail log. A log consisting essentially of a rotor towed through the water by a line attached to a distance-registering device secured at the taffrail.

tangent screw. A screw providing tangential movement along an arc, as that of a marine sextant.

telegraph buoy. A buoy used to mark the position of a submarine telegraph cable.

telemeter. The equipment for measuring any quantity, transmitting the results electrically to a distant point, and there recording the values measured.

temperature error. That instrument error due to nonstandard temperature.

terrestrial refraction. Atmospheric refraction of a ray of radiant energy from a point on or near the surface of the earth.

terrestrial triangle. A triangle on the surface of the earth, especially the navigational triangle.

theodolite. An optical surveying instrument for accurately measuring horizontal and vertical angles.

thermometer. An instrument for measuring temperature.

three-arm protractor. An instrument consisting of a circle graduated in degrees, to which is attached one fixed arm and two movable arms which can be clamped at any angle to the fixed arm, within the limits of the instrument.

tidal current. Current due to tidal action.

tidal current tables. Tables listing predictions of the times and speeds of tidal currents at various places, and other pertinent information.

tidal datum. A level of the sea, defined by some phase of the tide, from which water depths and heights of tide are reckoned.

tidal day. The period of the daily cycle of the tides, averaging about 24^h50^m in length.

tidal difference. The difference between the time or height of tides at a subordinate station and its reference station.

tidal wave. The ridge of water raised by tidal action, resulting in tides at various places. The expression is popularly but incorrectly used to refer to a tsunami or storm wave which overflows the land.

tide. The periodic rise and fall of the water surfaces of the earth due principally to the gravitational attraction of the moon and sun.

tide correction. That altitude correction due to tilting of the surface of the sea, as by a tide wave.

tide gage. An instrument for measuring the height of tide.

tide rips. Small waves formed by the meeting of opposing tidal currents or by a tidal current crossing an irregular bottom.

tide station. A place at which tide observations are made.

tide tables. Tables listing predictions of the times and heights of tides.

tide wave. The ridge of water raised by tidal action.

tilt error. That error introduced in the reading of an instrument due to tilt.

time. **1.** The hour of the day reckoned by the position of a celestial reference point relative to a reference celestial meridian. **2.** An elapsed interval.

time and altitude azimuth. An azimuth determined when meridian angle, declination, and altitude are known.

time azimuth. An azimuth determined when meridian angle, polar distance (or declination), and latitude are known.

time base. The sweep of a cathode ray tube, used for measuring time intervals.

time diagram. A diagram in which the celestial equator appears as a circle, and celestial meridians and hour circles appear as radial lines.

time meridian. Any meridian used as a reference for reckoning time, particularly zone time.

time sight. An observation of the altitude of a celestial body, made for the purpose of determining longitude, or the method of reducing such an observation.

time signal. A signal marking a specified time.

time tick. A time signal consisting of one or more short audible sounds.

time zone. An area in all parts of which the same time is kept.

topmark. A characteristic shape secured at the top of a buoy or beacon to aid in its identification.

trace. The line appearing on the face of a cathode ray tube when the visible dot repeatedly sweeps across the face of the tube.

track. The horizontal component of the path followed or expected to be followed by a vessel or a storm center.

track chart. A chart showing recommended, required, or established tracks, and usually indicating turning points, courses, and distances.

tracking. The process of following the movements of an object.

transfer. The distance a vessel moves perpendicular to its initial direction of motion in making a turn.

transit. 1. Meridian transit. **2.** A theodolite that can be reversed in its supports without being lifted from them.

transponder. A combined receiver and transmitter which transmits signals automatically when triggered by an incoming signal.

transverse Mercator projection. A map projection similar to a Mercator projection but with the cylinder rotated through 90°, so that it is tangent along a meridian.

traverse. A series of directions and distances, as the courses and speeds of a vessel zigzagging.

traverse sailing. A method of determining the equivalent course and distance made good by a vessel following a track consisting of a series of rhumb lines.

traverse table. A table giving relative values of various parts of plane right triangles, for use in solving such triangles.

tropical cyclone. A violent cyclone originating in the tropics.

tropic range. The difference in height between tropic higher high water and tropic lower low water.

tropic tides. The tides that occur when the moon is near its maximum declination, when the diurnal range tends to increase.

true amplitude. Amplitude relative to true east or west.

true azimuth. Azimuth relative to true north.

true bearing. Bearing relative to true north.

true course. Course relative to true north.

true heading. Heading relative to true north.

true north. The direction of the north geographical pole.

true wind. Wind relative to a fixed point on the earth.

tsunami. An ocean wave produced by a submarine earthquake, landslide, or volcanic action. Popularly called a "tidal wave" when it overflows the land.

turning buoy. A buoy marking a turn, as in a channel.

twilight. The periods of incomplete darkness following sunset or preceding sunrise.

twilight compass. A compass for indicating direction during twilight, particularly a sky compass.

ultra high frequency. Radio frequency of 300 to 3,000 megacycles per second.

ultrasonic depth finder. An echo sounder operating at a frequency above the audible range.

ultraviolet. Having a frequency immediately beyond the violet end of the visible spectrum.

uncorrecting. The process of converting true direction to magnetic, compass, or gyro direction, or magnetic direction to compass direction.

undercurrent. A current below the surface.

underwater navigation. Navigation of a submerged vessel.

unfavorable current. A current which decreases the speed of a vessel over the ground.

unfavorable wind. A wind which delays the progress of a craft in a desired direction.

unidirectional. In one direction only.

universal plotting sheet. A plotting sheet that can be used at various latitudes and any longitude.

universal time. Greenwich mean time.

upper air sounding. Determination of the characteristics of the upper air.

upper branch. That half of a meridian or celestial meridian from pole to pole which passes through a place or its zenith.

upper limb. That half of the limb (of a celestial body) having the greatest altitude.

upper transit. Transit across the upper branch of the celestial meridian.

variation. The angle between the magnetic and geographical meridians.

V-band. A radio-frequency band of 46,000 to 56,000 megacycles.

vector. A straight line representing both direction and magnitude.

vector diagram. A diagram of more than one vector drawn to the same scale and reference direction, and in correct position relative to each other.

vector quantity. A quantity having both magnitude and direction.

veer. Of the wind, (a) to change direction clockwise in the northern hemisphere and counterclockwise in the southern hemisphere, or (b) to shift aft.

velocity. Rate of motion in a given direction.

velocity ratio. The ratio of the speed of tidal currents at a subordinate station and its reference station.

vernal equinox. That point of intersection of the ecliptic and the celestial equator, occupied by the sun as it changes from south to north declination, on or about March 21, or the instant this occurs.

vernier. A scale or control used for interpolation in the reading of an instrument or for closer adjustment of any equipment.

vernier sextant. A marine sextant having a vernier used directly with the arc.

versine. One minus the cosine (1—cos).

vertical circle. A great circle of the celestial sphere, through the zenith and nadir, and hence perpendicular to the horizon.

very high frequency. Radio frequency of 30 to 300 megacycles per second.

very low frequency. Radio frequency of less than 30 kilocycles per second.

vigia. A rock or shoal the existence or position of which is doubtful.

visibility. The extreme horizontal distance at which prominent objects can be seen and identified by the unaided eye.

visible horizon. That line where earth and sky appear to meet.

vulgar establishment. The average interval of time between the transit (upper or lower) of the full or new moon and the next high water.

warm air mass. An air mass that is warmer than surrounding air, and usually warmer than the surface over which it is moving.

warm front. That line of discontinuity, at the earth's surface or at a horizontal plane aloft, where the forward edge of an advancing warm air mass is replacing a colder air mass.

warm sector. An area at the earth's surface bounded by the warm and cold fronts of a cyclone.

war time. Daylight saving time kept throughout the year during a war.

watch buoy. Station buoy.

watch error. The amount by which watch time differs from the correct time.

watch rate. The amount gained or lost by a watch or clock in unit time, usually seconds per day.

watch time. The hour of the day as indicated by a watch or clock.

wave. 1. An undulation or ridge on the surface of a liquid, or anything resembling this. 2. A disturbance propagated in such a manner that it may progress from point to point.

wave crest. The highest part of a wave.

wave direction. The direction *from* which waves are moving.

wave height. The distance from the trough to the crest of a wave, measured perpendicular to the direction of advance.

wave height correction. That altitude correction due to elevation of the visible horizon by waves.

wave length. The distance in the direction of advance between the same phase of consecutive waves.

wave period. The time interval between passage of successive wave crests at a fixed point.

wave train. A group of related waves, constituting a series.

wave trough. The lowest part of a wave, between two crests.

weather map. Synoptic chart.

weather signal. A visual signal displayed to indicate a weather forecast.

weather vane. A device to indicate the direction from which the wind blows.

westing. The distance a craft makes good to the west.

wind. Moving air, especially a mass of air having a common direction of motion.

wind current. A current created by the action of wind.

wind direction. The direction *from* which wind blows.

wind rose. A diagram showing the relative frequency and sometimes the average speed of the winds blowing from different directions in a specified region.

wind vane. A device to indicate wind direction.

wind wave. A wave generated by friction between wind and a fluid surface.

winter solstice. That point on the ecliptic occupied by the sun at maximum southerly declination, or the instant the sun occupies this position, about December 22.

wiping. The process of reducing the amount of permanent magnetism in a vessel by placing a single coil horizontally around the vessel and moving it, while energized, up and down along the sides of the vessel.

wire drag. A buoyed wire towed at a given depth to determine whether any isolated rocks, small shoals, etc., extend above that depth, or for determining the least depth of an area.

X-band. A radio-frequency band of 5,200 to 10,900 megacycles.

young ice. Newly formed ice.

zenith. That point of the celestial sphere vertically overhead.

zenithal projection. Azimuthal projection.

zenith distance. Angular distance from the zenith.

zodiac. That band of the sky extending 8° either side of the ecliptic.

zone description. The number, with its sign, that must be added to or subtracted from zone time to obtain Greenwich mean time.

zone time. The local mean time of a reference or zone meridian whose time is kept throughout a designated zone.

APPENDIX G

IDENTIFICATION OF NAVIGATIONAL STARS

Introduction.—The following summary is not intended as a substitute for a star finder such as H.O. 2102–D, or of a knowledge of the heavens, but is given as a supplementary reference to assist in locating the 57 stars included in the main listing in the *Nautical Almanac*, plus Polaris. The observer is assumed to be at about the average latitude of the United States, unless another latitude is indicated. If a celestial body is said to be *east* of another, it is lower in the sky if both are rising and higher if both are setting. A body *north* of another is nearer the north celestial pole. Directions refer to great circles on the celestial sphere. Figures referred to are the star charts of chapter XXII, which should be of assistance in interpreting the descriptions given. It is assumed the reader is familiar with such well-known configurations as the big dipper and *Orion*. Constellation names are given in *italics*.

Acamar crosses the celestial meridian near the southern horizon during evening twilight in February, and during morning twilight in August. It is part of the constellation *Eridanus*, the river, which is not a striking configuration. It is the faintest star listed among the 57 in the almanac, but is the brightest in its immediate vicinity. The nearest bright star is Achernar, about 20° away in a generally southwesterly direction. Dec. 40° S, SHA 316°, mag. 3.1. Fig. 2205.

Achernar, at the southern end of the inconspicuous constellation *Eridanus*, the river, is one of the brightest stars of the southern hemisphere. It is not visible north of latitude 33° N. It crosses the celestial meridian during evening twilight in January, and during morning twilight in early August. Nearly a straight line is formed by Fomalhaut, about 40° WNW; Achernar; and Canopus, about the same distance in the opposite direction. However, since these stars are widely separated, the relationship is not striking. Achernar forms large triangles with Acamar and Ankaa, Ankaa and Al Na'ir, and with Al Na'ir and Peacock. Dec. 57° S, SHA 336°, mag. 0.6. Fig. 2205.

Acrux is the brightest and most southerly star in the famed southern cross. It is not visible north of latitude 27° N. It crosses the celestial meridian during evening twilight in early June and during morning twilight in January. It is about 15° WSW of first magnitude Hadar and Rigil Kentaurus. Dec. 63° S, SHA 174°, mag. 1.1. Fig. 2207.

Adhara. About 10° S and a little to the east of Sirius is a small, approximately equilateral triangle of three second magnitude stars. Adhara is the westernmost and brightest of the three. It crosses the celestial meridian to the south during evening twilight in March, and during morning twilight in October. Dec. 29° S, SHA 256°, mag. 1.6. Fig. 2206.

Aldebaran. If the line formed by the belt of *Orion*, the hunter, is extended about 20° to the northwestward, and curved somewhat toward the north, it leads to first magnitude Aldebaran in *Taurus*, the bull. This is a group of stars forming a V. A long, curving line starting at Sirius extends through Procyon, Pollux, Capella, and Aldebaran. Dec. 16° N, SHA 292°, mag. 1.1. Fig. 2206.

Alioth is the third star from the outer end of the handle of the big dipper, and the brightest star of the group. Dec. 56°N, SHA 167°, mag. 1.7. Fig. 2207.

Alkaid is the star at the outer end of the handle of the big dipper, farthest from the bowl. It is the second brightest star of the group. Dec. 50°N, SHA 154°, mag. 1.9. Fig. 2207.

Al Na'ir is the westernmost of two second magnitude stars of nearly equal brightness about midway between first magnitude Fomalhaut, approximately 20° to the northeast, and second magnitude Peacock, about the same distance in the opposite direction. A curved line extending eastward from the southern cross passes through Hadar and Rigil Kentaurus and, if extended with less curvature, leads first to Peacock and then to Al Na'ir. This star forms triangles with Fomalhaut and Ankaa, Ankaa and Achernar, and with Achernar and Peacock. It is not visible north of latitude 43°N. It crosses the celestial meridian during evening twilight early in December, and during morning twilight in June. Dec. 47°S, SHA 29°, mag. 2.2. Figs. 2205, 2208.

Alnilam is the middle star of the belt of *Orion*, the hunter. Dec. 1°S, SHA 277°, mag. 1.8. Fig. 2206.

Alphard, a second magnitude star, is the brightest in the inconspicuous constellation *Hydra*, the water monster. The nearest bright star is first magnitude Regulus, about 20° NNE. It is about midway between the horizon and zenith when it crosses the celestial meridian to the southward during evening twilight in late April, and during morning twilight in November. Dec. 8°S, SHA 219°, mag. 2.2. Fig. 2207.

Alphecca is the brightest star of *Corona Borealis*, the northern crown, about 20°ENE of first magnitude Arcturus. It forms a triangle with Arcturus and Alkaid. It crosses the celestial meridian near the zenith during evening twilight in July, and during morning twilight in February. Dec. 27°N, SHA 127°, mag. 2.3. Figs. 2207, 2208.

Alpheratz, a second magnitude star, is at the northeast corner of the great square of *Pegasus*, the winged horse, and is the brightest of the four stars forming the square. It crosses the celestial meridian near the zenith during evening twilight early in January, and during morning twilight in July. Dec. 29°N, SHA 359°, mag. 2.2. Fig. 2205.

Altair is at the southern vertex of a large, nearly right triangle which is a conspicuous feature of the evening sky in late summer and in autumn. The right angle is at Vega and the northern vertex is at Deneb. All three are first magnitude stars. Two fainter stars close to Altair, one on each side in a line through Vega, form a characteristic pattern making Altair one of the easiest stars to identify. It crosses the celestial meridian during evening twilight in October, and during morning twilight in May. Dec. 9°N, SHA 63°, mag. 0.9. Fig. 2208.

Ankaa, a second magnitude star, is the brightest star in inconspicuous *Phoenix*. It is surrounded by and forms a series of triangles with Diphda, Fomalhaut, Al Na'ir, Achernar, and Acamar. It crosses the celestial meridian low in the southern sky in January, and during morning twilight in July. Dec. 42°S, SHA 354°, mag. 2.4. Fig. 2205.

Antares is the brightest star in the conspicuous constellation *Scorpio*, the scorpion, which is low in the southern sky during evening twilight in late July, and morning twilight in late February. No other first magnitude star is within 40° of Antares and none toward the north is within 60°. It has a noticeable reddish hue and in appearance somewhat resembles Mars, which is occasionally near it in the sky. Dec. 26°S, SHA 113°, mag. 1.2. Fig. 2208.

Arcturus. The curved line along the stars forming the handle of the big dipper, if continued in a direction away from the bowl, passes through brilliant, first magnitude Arcturus. The distance from Alkaid, at the end of the big dipper, to Arcturus is a little more than the length of the dipper. Arcturus forms a large triangle with Alkaid and Alphecca. Dec. 19° N, SHA 147°, mag. 0.2. Figs. 2207, 2208.

Atria is the brightest of three stars forming a small triangle called *Triangulum Australe*, the southern triangle, not far from the south celestial pole. It is not seen north of latitude 21° N. A line through the east-west arm of the southern cross, if continued toward the east and curved somewhat toward the south, leads first to Hadar, then to Rigil Kentaurus, then, by curving more sharply, to the northernmost star of the triangle, and finally to Atria, only about 21° from the south celestial pole. Dec. 69° S, SHA 109°, mag. 1.9. Fig. 2207.

Avior is the westernmost star of *Vela*, the sails, or false southern cross, about 30° WNW of the true southern cross, about 15° ESE of the brilliant Canopus, and nearly enclosed within a large triangle formed by Canopus, Suhail, and Miaplacidus. It is not visible north of latitude 31° N. Below this, it crosses the celestial meridian low in the southern sky during evening twilight in April, and morning twilight in early November. Dec. 59°S, SHA 235°, mag. 1.7. Figs. 2206, 2207.

Bellatrix is a second magnitude star north and a little west of the belt of *Orion*, the hunter. It is about equidistant from the belt and first magnitude, red Betelgeuse. Bellatrix is at the northwest corner of a box surrounding the belt of *Orion*. Dec. 6° N, SHA 279°, mag. 1.7. Fig. 2206.

Betelgeuse is a conspicuous, reddish star of variable brightness about 10° north and a little east of the belt of *Orion*, the hunter. A line through the center of the belt and perpendicular to it passes close to red Betelgeuse to the north and blue Rigel about the same distance south of the belt. Betelgeuse and Rigel are at opposite corners of a box surrounding the belt of *Orion*. Dec. 7° N, SHA 272°, mag. 0.1–1.2 (variable). Fig. 2206.

Canopus, second brightest star in the sky, is about 35° south of Sirius. A line extending eastward through the belt of *Orion* and curving toward the south passes first through Sirius, then through the small triangle of which Adhara is the brightest star, and finally to Canopus, which forms a large, almost equilateral triangle with Suhail and Miaplacidus. This triangle nearly encloses *Vela*, the sails or false southern cross, about 20°ESE of Canopus. Canopus is not visible north of latitude 37°N. It is on the edge of the Milky Way and while many relatively bright stars are nearby, none in the immediate vicinity of Canopus approaches it in brightness. Dec. 53° S, SHA 264°, mag. (—)0.9. Fig. 2206.

Capella is a brilliant star about 45° north of the belt of *Orion*, the hunter. A curved line starting at Sirius and extending through Procyon, Pollux, Capella, Aldebaran, the belt of *Orion*, and back to Sirius forms an inverted tear-drop figure with Capella at the top and the various parts being about equally spaced along the curve. Capella crosses the celestial meridian near the zenith during evening twilight in early March, and during morning twilight in late September. Dec. 46° N, SHA 282°, mag. 0.2. Fig. 2206.

Deneb is a bright star at the northeastern vertex of a large, nearly right triangle formed by Altair, Vega, and Deneb, the right angle being at Vega. These three stars are the brightest in the eastern sky during summer evenings. Deneb is not as bright as the other two, but is the brightest star in the constellation *Cygnus*, the swan. It crosses the celestial meridian near the zenith during evening twilight in November, and during morning twilight in late May. Dec. 45° N, SHA 50°, mag. 1.3. Fig. 2208.

Denebola, in *Leo*, the lion, is a second magnitude star at the opposite end of the constellation from Regulus. A straight line from Regulus, on the west, to Arcturus, on the east, passes close to Denebola, which is somewhat nearer Regulus. Denebola crosses the celestial meridian to the south during evening twilight in May, and during morning twilight in December. Dec. 15° N, SHA 183°, mag. 2.2. Fig. 2207.

Diphda. A line extending southward through the eastern side of the great square of *Pegasus*, the winged horse, and curving slightly toward the east, leads to second magnitude Diphda. The distance from the southern star of *Pegasus* to Diphda is about twice the length of one side of the square. Diphda is part of the inconspicuous constellation *Cetus*, the whale. The only nearby first magnitude star is Fomalhaut, about 25° in a generally southwest direction. Diphda, Fomalhaut, and Ankaa form a nearly equilateral triangle. Dec. 18° S, SHA 350°, mag. 2.2. Fig. 2205.

Dubhe forms the outer rim of the bowl of the big dipper. It and Merak (not one of the 57 navigational stars) are the two "pointers" used to locate Polaris, Dubhe being the one nearer the pole star. Dec. 62° N, SHA 195°, mag. 2.0. Fig. 2207.

Elnath is a second magnitude star between Capella, about 15° to the north, and Betelgeuse, about 20° to the south. It is a little north of a line connecting Aldebaran and Pollux. It is at the end of the northern fork of V-shaped *Taurus*, the bull. Aldebaran is the principal star at the closed end of the V. This constellation is approximately 25° NNW of *Orion*, the hunter. Dec. 29° N, SHA 279°, mag. 1.8. Fig. 2206.

Eltanin is the southernmost and brightest star in the inconspicuous constellation *Draco*, the dragon, south and somewhat east of the little dipper. A straight line extending northwestward through Altair and its two fainter companions passes first through brilliant Vega, and, about 15° beyond, to second magnitude Eltanin. Eltanin crosses the celestial meridian high in the sky toward the north during evening twilight in early September, and during morning twilight in late March. Dec. 51°N, SHA 91°, mag. 2.4. Fig. 2208.

Enif is a third magnitude star approximately midway between Altair, about 25° west, and Markab, about 20° ENE. From Markab, at the southwestern corner of the great square of *Pegasus*, the winged horse, a line extending in a generally west-southwesterly direction passes through two almost equally spaced fourth magnitude stars. From the second of these, a line about 5° long extending in a northwesterly direction leads to Enif. Enif crosses the celestial meridian to the south during evening twilight in November, and during morning twilight in June. Dec. 10° N, SHA 35°, mag. 2.5. Figs. 2205, 2208.

Fomalhaut is a first magnitude star well separated from stars of comparable brightness and from conspicuous configurations. A line through the western side of the great square of *Pegasus*, the winged horse, and extended about 45° toward the south passes close to Fomalhaut, which forms two large, nearly equilateral triangles with Diphda and Ankaa and with Ankaa and Al Na'ir. Dec. 30°S, SHA 16°, mag. 1.3. Fig. 2205.

Gacrux is the northernmost star of the southern cross. It is bright for a second magnitude star, but its brilliance is overshadowed by the brighter β *Crucis* (not listed among the 57 navigational stars) and Acrux, the two brightest stars of the southern cross, and by Hadar and Rigil Kentaurus, about 15° ESE. Gacrux crosses the celestial meridian during evening twilight in early June, and during morning twilight in late December, but is not visible north of latitude 33° N. Dec. 57° S, SHA 173°, mag. 1.6. Fig. 2207.

Gienah is a third magnitude star, the brightest in the constellation *Corvus*, the crow. A long, sweeping arc starting with the handle of the big dipper and extending

successively through Arcturus and Spica leads to this relatively small, four-sided figure made up of third magnitude stars. Gienah is at the northwest corner. It crosses the celestial meridian during evening twilight in late May, and during morning twilight in December. Dec. 17° S, SHA 177°, mag. 2.8. Fig. 2207.

Hadar is a first magnitude star about 10° east of the southern cross, and about 5° west of Rigil Kentaurus, the brightest of several bright stars in this part of the sky. Dec. 60° S, SHA 150°, mag. 0.9. Fig. 2207.

Hamal is the brightest star of the inconspicuous constellation *Aries*, the ram. A line through the center of the great square of *Pegasus*, the winged horse, extended about 25° east, and curved slightly toward the north, leads to Hamal. It is over the meridian to the south during evening twilight in January, and during morning twilight in August. Dec. 23° N, SHA 329°, mag. 2.2. Fig. 2205.

Kaus Australis is near the southern end of a group of second and third magnitude stars forming the constellation *Sagittarius*, the archer, about 25° ESE of Antares, in *Scorpio*, the scorpion. It is about 10° SW of Nunki, also in *Sagittarius*, and about the same distance ENE of Shaula, in *Scorpio*. With Antares, Sabik, and Nunki, it forms a large, poorly defined box. It is over the meridian to the south during evening twilight in September and during morning twilight in April. Dec. 34° S, SHA 85°, mag. 2.0. Fig. 2208.

Kochab forms the outer rim of the bowl of the little dipper, at the opposite end from Polaris, about 15° north. It is directly above the pole during evening twilight in early July and during morning twilight in January; and directly below the pole, low in the northern sky, during evening twilight of early February and morning twilight of late August. Dec. 74° N, SHA 137°, mag. 2.2. Fig. 2208.

Markab is the star at the southwest corner of the great square of *Pegasus*, the winged horse, at the opposite corner from Alpheratz. It is over the celestial meridian to the south during evening twilight in December, and during morning twilight late in June. Dec. 15° N, SHA 14°, mag. 2.6. Fig. 2205.

Menkar is a third magnitude star at the eastern end of the inconspicuous constellation *Cetus*, the whale. No bright stars are nearby. A straight line from Aldebaran extending about 25° in the direction indicated by the point of the V of *Taurus*, the bull, leads to Menkar. A long, straight line from Fomalhaut east-northeastward through Diphda, and extended about 40°, leads to Menkar. It crosses the celestial meridian during evening twilight in February, and during morning twilight in August. Dec. 4° N, SHA 315°, mag. 2.8. Figs. 2205, 2206.

Menkent is a second magnitude star about 25° north of Hadar and about 30° northeast of the southern cross. A line from Gienah across the opposite corner of the small, four-sided *Corvus*, the crow, and then curving a little toward the east, leads to Menkent. A number of third magnitude stars are nearby, but they do not form a conspicuous configuration. With Antares and Rigil Kentaurus, Menkent forms a large triangle. It crosses the celestial meridian low in the southern sky during evening twilight in late June and during morning twilight in early January. Dec. 36° S, SHA 149°, mag. 2.3. Figs. 2207, 2208.

Miaplacidus is a second magnitude star about 10° south of the false southern cross. It is the nearest of the 57 navigational stars to the south celestial pole, about 20° away, and is not visible north of latitude 20° N. With Suhail and brilliant Canopus it forms a large, nearly equilateral triangle almost enclosing the false southern cross. South of latitude 20° S, it does not set, but circles the south celestial pole in a clockwise direction, reaching its maximum altitude above the pole during evening twilight in early May

and during morning twilight in November. Dec. 70°S, SHA 222°, mag. 1.8. Figs. 2206, 2207.

Mirfak is a second magnitude star at the northeastern end of a gently curving line extending in a northeasterly direction from Alpheratz at the northeastern corner of the great square of *Pegasus*, the winged horse, through two other second magnitude stars, Mirach and Almach, not included among the 57 navigational stars. Mirfak is about 25° east and a little south of *Cassiopeia*, and about 20° WNW of Capella. A line from Kochab through Polaris, and curved slightly toward the east, leads to Mirfak. Dec. 50°N, SHA 310°, mag. 1.9. Figs. 2205, 2206.

Nunki is the more northerly of the two brightest stars of a group of second and third magnitude stars forming the constellation *Sagittarius*, the archer, about 30°E of Antares. It is about 10° NE of Kaus Australis, also in *Sagittarius*. With Sabik, Antares, and Kaus Australis, it forms a large, poorly defined box. It is over the meridian to the south during evening twilight in early October and during morning twilight in April. Dec. 26°S, SHA 77°, mag. 2.1. Fig. 2208.

Peacock, the brightest star in the southern constellation of the same name, is not a part of a conspicuous configuration of stars. A curved line extending eastward from the southern cross passes through Hadar and Rigil Kentaurus and, if extended with less curvature, leads to Peacock, about 30° southeast of *Scorpio*, the scorpion, and about 20° southwest of Al Na'ir. With Al Na'ir and Achernar it forms a large, poorly defined triangle. It crosses the celestial meridian during evening twilight in early November, and during morning twilight in late May, but is not visible north of latitude 33°N. Dec. 57°S, SHA 54°, mag. 2.1. Figs. 2205, 2208.

Polaris is not listed among the 57 navigational stars, but is treated separately because it is less than 1° from the north celestial pole. It is about midway between the big dipper and *Cassiopeia*. A line through Dubhe and Merak (not one of the 57 navigational stars), the pointers forming the outer side of the bowl of the big dipper, if extended northward for about 30°, leads almost directly to Polaris. A line extending north from Alpheratz at the northwest corner of the great square of *Pegasus*, the winged horse, passes through Caph (not one of the 57 navigational stars) in *Cassiopeia* and then Polaris at about equal intervals. Dec. 89°N, SHA 332°, mag. 2.1. Figs. 2205–2208.

Pollux is the brighter of the "twins of *Gemini*," two relatively bright stars about 45°NE of *Orion*, the hunter, and about 45°ENE of Aldebaran. A curved line starting at Sirius extends through Procyon, Pollux, and Capella, all first magnitude stars. Dec. 28°N, SHA 244°, mag. 1.2. Fig. 2206.

Procyon is a bright star about 30° east of *Orion*, the hunter. A curved line starting at Sirius extends through Procyon, Pollux, and Capella, all first magnitude stars. Dec. 5°N, SHA 246°, mag. 0.5. Fig. 2206.

Rasalhague forms a large, nearly equilateral triangle with Altair and Vega, Rasalhague being at the western vertex. Both of the other stars are considerably brighter than Rasalhague. It crosses the celestial meridian to the south during evening twilight in early September, and during morning twilight in late March. Dec. 13°N, SHA 97°, mag. 2.1. Fig. 2208.

Regulus is at the opposite end of *Leo*, the lion, from Denebola, and is the brightest star of the constellation. A line through Dubhe and Merak (not one of the 57 navigational stars), the pointers by which Polaris is usually identified, extended about 45° *southward*, and curved slightly toward the west, leads to Regulus, which forms the southern end of the handle of the sickle, part of *Leo*. Dec. 12° N, SHA 209°, mag. 1.3. Fig. 2207.

Rigel is a brilliant bluish star about 10°S and a little to the west of the belt of *Orion*, the hunter. A line through the center of the belt and perpendicular to it passes close to blue Rigel to the south and red Betelgeuse about the same distance north of the belt. Rigel and Betelgeuse are at opposite corners of a box surrounding the belt of *Orion*. Dec. 8°S, SHA 282°, mag. 0.3. Fig. 2206.

Rigil Kentaurus is the brighter and more easterly of two first magnitude stars about 15° east of the southern cross. It is over the meridian during evening twilight in early July, and during morning twilight in late January, but is not visible north of latitude 29°N. Dec. 61°S, SHA 141°, mag. 0.1. Figs. 2207, 2208.

Sabik is part of the inconspicuous constellation *Ophiuchus*, the serpent holder, about 20° north of *Scorpio*, the scorpion. With Antares, Kaus Australis, and Nunki, it forms a large, poorly defined box in the southern sky on summer evenings. Sabik crosses the celestial meridian during evening twilight in August, and during morning twilight in March. Dec. 16°S, SHA 103°, mag. 2.6. Fig. 2208.

Schedar is the southernmost star of the W (or M) of *Cassiopeia*, on the opposite side of Polaris from the big dipper. It is the second star from the leading edge of this configuration as it circles the north celestial pole. Dec. 56°N, SHA 351°, mag. 2.5. Figs. 2205, 2206, 2208.

Shaula is a second magnitude star marking the end of the tail of *Scorpio*, the scorpion, at the opposite end from Antares. This constellation is low in the southern sky on summer evenings. Shaula is about 15° southeast of Antares and about 10° WSW of Kaus Australis. It crosses the celestial meridian during evening twilight in early September, and during morning twilight in March. Dec. 37°S, SHA 97°, mag. 1.7. Fig. 2208.

Sirius, the brightest star in the heavens, is in the constellation *Canis Major*, the "large dog" of *Orion*, the hunter. The line formed by the belt of *Orion*, if extended about 20° to the eastward and curved toward the south, leads to Sirius. Dec. 17°S, SHA 259°, mag. (−)1.6. Fig. 2206.

Spica is the brightest star of *Virgo*, the virgin, an inconspicuous constellation on the celestial equator to the south during evening twilight in early summer. The curved line along the stars forming the handle of the big dipper, if continued in a direction away from the pointers, passes through Arcturus and then Spica. The distance between Alkaid, at the end of the big dipper, and Arcturus is about the same as that between Arcturus and Spica, and is a little more than the length of the big dipper. Spica crosses the celestial meridian during evening twilight in June, and during morning twilight late in December. Dec. 11°S, SHA 159°, mag. 1.2. Fig. 2207.

Suhail is one of a number of second magnitude stars extending along the Milky Way between Sirius and the southern cross. It is about 10° north of the false southern cross, which is nearly enclosed by a large, nearly equilateral triangle formed by Suhail, Canopus, and Miaplacidus. Canopus and Suhail are on opposite edges of the Milky Way, with a number of second magnitude stars between them. A straight line extending eastward through the east-west arm of the southern cross leads to Suhail, about 35° away. In the southern United States, Suhail crosses the celestial meridian near the southern horizon during evening twilight in April, and during morning twilight in November. Dec. 43° S, SHA 223°, mag. 2.2. Figs. 2206, 2207.

Vega is the brightest star north of the celestial equator, and the third brightest in the entire sky. It is at the western vertex and the nearly right angle of a large triangle which is a conspicuous feature of the evening sky in late summer and in autumn. The other two stars of the triangle are Altair and Deneb, both of the first magnitude.

Vega passes through the zenith approximately at latitude 38°45′N during evening twilight in September and during morning twilight in April. Dec. 39°N, SHA 81°, mag. 0.1. Fig. 2208.

Zubenelgenubi, a third magnitude star, is the southern (or western) basket of *Libra*, the balance. The boxlike *Libra* is about 25° WNW of Antares, in *Scorpio*, the scorpion. A long line extending eastward from Alphard, between Gienah and Spica, leads to Zubenelgenubi. Dec. 16°S, SHA 138°, mag. 2.9. Figs. 2207, 2208.

APPENDIX H

NAVIGATIONAL STARS AND THE PLANETS

Name	Pronunciation	Bayer name	Origin of name	Meaning of name	Distance*
Acamar	ā'kȧ·mär	θ Eridani	Arabic	another form of Achernar	120
Achernar	ā'kēr·när	α Eridani	Arabic	end of the river (Eridanus)	72
Acrux	ā'krŭks	α Crucis	Modern	coined from Bayer name	220
Adhara	ȧ·dā'rȧ	ε Canis Majoris	Arabic	the virgin(s)	350
Aldebaran	ăl dĕb'ȧ·răn	α Tauri	Arabic	follower (of the Pleiades)	64
Alioth	ăl'ĭ·ŏth	ε Ursa Majoris	Arabic	another form of Capella	49
Alkaid	ăl·kād'	η Ursa Majoris	Arabic	leader of the daughters of the bier	190
Al Na'ir	ăl·nār'	α Gruis	Arabic	bright one (of the fish's tail)	90
Alnilam	ăl'nĭ·lăm	ε Orionis	Arabic	string of pearls	410
Alphard	ăl'färd	α Hydrae	Arabic	solitary star of the serpent	200
Alphecca	ăl·fĕk'ȧ	α Corona Borealis	Arabic	feeble one (in the crown)	76
Alpheratz	ăl·fē'răts	α Andromeda	Arabic	the horse's navel	120
Altair	ăl·tār'	α Aquilae	Arabic	flying eagle or vulture	16
Ankaa	än'kä	α Phoenicis	Arabic	coined name	93
Antares	ăn·tā'rēz	α Scorpii	Greek	rival of Mars (in color)	250
Arcturus	ärk·tū'rŭs	α Bootis	Greek	the bear's guard	37
Atria	ăt'rĭ·ȧ	α Trianguli Australis	Modern	coined from Bayer name	130
Avior	ā'vĭ·ôr	ε Carinae	Modern	coined name	350
Bellatrix	bĕ·lā'trĭks	γ Orionis	Latin	female warrior	250
Betelgeuse	bĕt'ĕl·jūz	α Orionis	Arabic	the arm pit (of Orion)	300
Canopus	kȧ·nō'pŭs	α Carinae	Greek	city of ancient Egypt	230
Capella	kȧ·pĕl'ȧ	α Aurigae	Latin	little she-goat	46
Deneb	dĕn'ĕb	α Cygni	Arabic	tail of the hen	600
Denebola	dĕ·nĕb'ō·lȧ	β Leonis	Arabic	tail of the lion	42
Diphda	dĭf'dȧ	β Ceti	Arabic	the second frog (Fomalhaut was once the first)	57
Dubhe	dŭb'ē	α Ursa Majoris	Arabic	the bear's back	100
Elnath	ĕl'năth	β Tauri	Arabic	one butting with horns	130
Eltanin	ĕl·tā'nĭn	γ Draconis	Arabic	head of the dragon	150
Enif	ĕn'ĭf	ε Pegasi	Arabic	nose of the horse	250
Fomalhaut	fō'măl·ôt	α Piscis Austrini	Arabic	mouth of the southern fish	23
Gacrux	gā'krŭks	γ Crucis	Modern	coined from Bayer name	72
Gienah	jē'nȧ	γ Corvi	Arabic	right wing of the raven	136
Hadar	hā'där	β Centauri	Modern	leg of the centaur	200
Hamal	hăm'ȧl	α Arietis	Arabic	full-grown lamb	76
Kaus Australis	kôs ôs·trā'lĭs	ε Sagittarii	Ar., L.	southern part of the bow	163
Kochab	kō'kăb	β Ursa Minoris	Arabic	shortened form of "north star" (named when it was that, c. 1500 BC–AD 300)	100
Markab	mär'kăb	α Pegasi	Arabic	saddle (of Pegasus)	100
Menkar	mĕn'kär	α Ceti	Arabic	nose (of the whale)	1,100
Menkent	mĕn'kĕnt	θ Centauri	Modern	shoulder of the centaur	55
Miaplacidus	mī'ȧ·plăs'ĭ·dŭs	β Carinae	Ar., L.	quiet or still waters	86
Mirfak	mĭr'făk	α Persei	Arabic	elbow of the Pleiades	130
Nunki	nŭn'kē	σ Sagittarii	Bab.	constellation of the holy city (Eridu)	150
Peacock	pē'kŏk	α Pavonis	Modern	coined from English name of constellation	250
Polaris	pō·lā'rĭs	α Ursa Minoris	Latin	the pole (star)	450
Pollux	pŏl'ŭks	β Geminorum	Latin	Zeus' other twin son (Castor, α Geminorum, is first twin)	33
Procyon	prō'sĭ·ŏn	α Canis Minoris	Greek	before the dog (rising before the dog star, Sirius)	11
Rasalhague	răs'ăl·hā'gwē	α Ophiuchi	Arabic	head of the serpent charmer	67
Regulus	rĕg'ū·lŭs	α Leonis	Latin	the prince	67
Rigel	rī'jĕl	β Orionis	Arabic	foot (left foot of Orion)	500
Rigil Kentaurus	rī'jĭl kĕn·tô'rŭs	α Centauri	Arabic	foot of the centaur	4.3
Sabik	sā'bĭk	η Ophiuchi	Arabic	second winner or conqueror	69
Schedar	shĕd'ȧr	α Cassiopeiae	Arabic	the breast (of Cassiopeia)	360
Shaula	shô'lȧ	λ Scorpii	Arabic	cocked-up part of the scorpion's tail	200
Sirius	sĭr'ĭ·ŭs	α Canis Majoris	Greek	the scorching one (popularly, the dog star)	8.6
Spica	spī'kȧ	α Virginis	Latin	the ear of corn	155
Suhail	sōō·hāl'	λ Velorum	Arabic	shortened form of Al Suhail, one Arabic name for Canopus	200
Vega	vē'gȧ	α Lyrae	Arabic	the falling eagle or vulture	27
Zubenelgenubi	zōō·bĕn'ĕl·jē·nū'bē	α Librae	Arabic	southern claw (of the scorpion)	66

PLANETS

Name	Pronunciation	Origin of name	Meaning of name
Mercury	mûr'kū·rĭ	Latin	god of commerce and gain
Venus	vē'nŭs	Latin	goddess of love
Earth	ûrth	Mid. Eng.	—
Mars	märz	Latin	god of war
Jupiter	jōō'pĭ·tēr	Latin	god of the heavens, identified with the Greek Zeus, chief of the Olympian gods
Saturn	săt'ērn	Latin	god of seed-sowing
Uranus	ū'rȧ·nŭs	Greek	the personification of heaven
Neptune	nĕp'tūn	Latin	god of the sea
Pluto	plōō'tō	Greek	god of the lower world (Hades)

Guide to pronunciations:
fāte, ădd, finăl, làst, ȧbound, ärm; bē, ĕnd, camĕl, readēr; īce, bĭt, anĭmal; ōver, pōetic, hŏt, lôrd, mōōn; cūbe, ūnite, tŭb, circŭs, ûrn

*Distances in light-years. One light-year equals approximately 63,300 AU, or 5,880,000,000,000 miles. Authorities differ on distances of the stars; the values given are representative.

APPENDIX I

CONSTELLATIONS

Name	Pronunciation	Genitive	Pronunciation	Meaning	Navigational stars or approximate position
Andromeda*	ăn·drŏm′·ḗ·dȧ	Andromedae	ăn·drŏm′ḗ·dē	Andromeda [the chained woman]†	Alpheratz
Antlia	ănt′lĭ·ȧ	Antliae	ănt′lĭ·ē	(air) pump††	d 35°S, SHA 210°
Apus	ā′pŭs	Apodis	ăp′ŏ·dĭs	bird of paradise	d 75°S, SHA 120°
Aquarius (♒)*	ȧ·kwâr′ĭ·ŭs	Aquarii	ȧ·kwâr′ĭ·ī	water carrier	d 5°S, SHA 25°
Aquila*	ăk′wĭ·lȧ	Aquilae	ăk′wĭ·lē	eagle	Altair
Ara*	ā′rȧ	Arae	ā′rē	altar	d 55°S, SHA 100°
Aries (♈)*	ā′rĭ·ēz	Arietis	ȧ·rī′ḗ·tĭs	ram	Hamal
Auriga*	ô·rī′gȧ	Aurigae	ô·rī′jē	charioteer	Capella
Bootes*	bô·ō′tēz	Bootis	bȯ·ō′tĭs	herdsman	Arcturus
Caelum	sē′lŭm	Caeli	sē′lī	graving tool	d 40°S, SHA 290°
Camelopardalis	kȧ·mĕl′ȯ·pär′dȧ·lĭs	Camelopardalis	kȧ·mĕl′ȯ·pär′dȧ·lĭs	giraffe	d 70°N, SHA 275°
Cancer (♋)*	kăn′sẽr	Cancri	kăng′krī	crab	d 20°N, SHA 230°
Canes Venatici	kā′nēz vḗ·năt′ĭ·sī	Canum Venaticorum	kā′nŭm vḗ·năt′ĭ·kō′rŭm	hunting dogs	d 40°N, SHA 165°
Canis Major*	kā′nĭs mā′jẽr	Canis Majoris	kā′nĭs mȧ·jō′rĭs	larger dog	Adhara, Sirius
Canis Minor*	kā′nĭs mī′nẽr	Canis Minoris	kā′nĭs mĭ·nō′rĭs	smaller dog	Procyon
Capricornus (♑)	kăp′rĭ·kôr′nŭs	Capricorni	kăp′rĭ·kôr′nī	horned goat	d 20°S, SHA 45°
Carina**	kȧ·rī′nȧ	Carinae	kȧ·rī′nē	keel	Avior, Canopus, Miaplacidus
Cassiopeia*	kăs′ĭ·ȯ·pē′yȧ	Cassiopeiae	kăs′ĭ·ȯ·pē′yē	Cassiopeia [the lady in the chair]†	Schedar
Centaurus*	sĕn·tô′rŭs	Centauri	sĕn·tô′rī	centaur	Hadar, Menkent, Rigil Kentaurus
Cepheus*	sē′fūs	Cephei	sē′fḗ·ī	Cepheus [the shepherd]†	d 75°N, SHA 15°
Cetus*	sē′tŭs	Ceti	sē′tī	whale	Diphda, Menkar
Chamaeleon	kȧ·mē′lḗ·ŭn	Chamaeleontis	kȧ·mē′lḗ·ŏn′tĭs	chameleon	d 80°S, SHA 200°
Circinus	sûr′sĭ·nŭs	Circini	sûr′sĭ·nī	pair of compasses	d 65°S, SHA 140°
Columba	kȯ·lŭm′bȧ	Columbae	kȯ·lŭm′bē	dove	d 35°S, SHA 275°
Coma Berenices	kō′mȧ bẽr·ḗ·nī′sēz	Comae Berenices	kō′mē bẽr′ḗ·nī′sēz	Berenice's hair	d 25°N, SHA 170°
Corona Australis*	kȯ·rō′nȧ ôs·trā′lĭs	Coronae Australis	kȯ·rō′nē ôs·trā′lĭs	southern crown	d 40°S, SHA 80°
Corona Borealis*	kȯ·rō′nȧ bō′rḗ·ā′lĭs	Coronae Borealis	kȯ·rō′nē bō′rḗ·ā′lĭs	northern crown	Alphecca
Corvus*	kôr′vŭs	Corvi	kôr′vī	crow	Gienah
Crater*	krā′tẽr	Crateris	krȧ·tē′rĭs	cup	d 15°S, SHA 190°
Crux	krŭks	Crucis	kro͞o′sĭs	cross	Acrux, Gacrux
Cygnus*	sĭg′nŭs	Cygni	sĭg′nī	swan	Deneb
Delphinus*	dĕl·fī′nŭs	Delphini	dĕl·fī′nī	dolphin	d 15°N, SHA 50°
Dorado	dȯ·rä′dō	Doradus	dȯ·rä′dŭs	dorado [a fish]†	d 60°S, SHA 285°
Draco*	drā′kō	Draconis	drȧ·kō′nĭs	dragon	Eltanin
Equuleus*	ḗ·kwo͞o′lḗ·ŭs	Equulei	ḗ·kwo͞o′lḗ·ī	colt	d 10°N, SHA 40°
Eridanus*	ḗ·rĭd′ȧ·nŭs	Eridani	ḗ·rĭd′ȧ·nī	Eridanus [a river]†	Acamar, Achernar
Fornax	fôr′năks	Fornacis	fôr·nā′sĭs	furnace	d 30°S, SHA 320°
Gemini (♊)*	jĕm′ĭ·nī	Geminorum	jĕm′ĭ·nō′rŭm	twins	Pollux
Grus	grŭs	Gruis	gro͞o′ĭs	crane [a bird]†	Al Na'ir
Hercules*	hûr′kû·lēz	Herculis	hûr′kû·lĭs	Hercules [mythological hero]†	d 30°N, SHA 100°
Horologium	hŏr′ȯ·lō′jĭ·ŭm	Horologii	hŏr′ȯ·lō′jĭ·ī	clock	d 50°S, SHA 310°
Hydra*	hī′drȧ	Hydrae	hī′drē	water monster	Alphard
Hydrus	hī′drŭs	Hydri	hī′drī	water snake	d 70°S, SHA 320°
Indus	ĭn′dŭs	Indi	ĭn′dī	Indian	d 60°S, SHA 35°

Zodiacal constellations are given in bold type, with their symbols.
*One of the original constellations of Ptolemy.
**Part of the single constellation Argo Navis of Ptolemy.
†Parts within brackets are amplifications of the meanings of constellation names.
††Parts within parentheses are the meanings of words deleted from former, more complete constellation names.

APPENDIX J

BUOYAGE SYSTEMS

With modifications, two systems of buoyage are in general use throughout the world. These are the **lateral system** and the **cardinal system.**

The lateral system is best suited for well-defined channels. The location of each buoy indicates the direction of the danger it marks relative to the course which should normally be followed. Thus, a buoy which should be kept on the port hand lies between the vessel and the danger when the buoy is abeam to port, approximately.

In principle, the positions of marks in the lateral system are determined by the general direction taken by the mariner when approaching a harbor, river, estuary, or other waterway from seaward, and may also be determined with reference to the main stream of flood current. The application of this principle is defined, as required, by nautical documents such as sailing directions.

The cardinal system is best suited for coasts with numerous rocks, shoals, and islands, and for dangers in the open sea. The location of each buoy indicates the approximate true bearing of the danger it marks. Thus, an eastern quadrant buoy marks a danger, such as a shoal, which lies to the west of the buoy, approximately.

Although almost all of the major maritime nations have used either the lateral or the cardinal system for many years, details such as the shapes and colors of the buoys and the characteristics and colors of lighted aids generally have varied from country to country. With the passage of time and the increase in maritime communication between countries, the desirability of a uniform system of buoyage has become increasingly apparent. Consequently, over the past century a number of attempts have been made to standardize the various systems of buoyage. International conferences have been held on the subject and recommendations have been made. These recommendations have often been conflicting, however, and although the differences in the various methods as applied to the cardinal system are comparatively slight, two distinct methods of applying the lateral system have evolved. The major discrepancy has been in the colors of the buoys and of their lights.

In 1889 the *International Marine Conference* held in Washington, D. C., recommended that in the lateral system starboard hand buoys be painted red and port hand buoys black. With the introduction of lighted aids to navigation, these recommendations logically led to the use, by nations which had accepted the recommendation, of red or white lights on the starboard side and green or white lights on the port side.

In 1936 in the most recent international pronouncement on the subject, a League of Nations subcommittee recommended a coloring system diametrically opposed to the 1889 proposal. This is part of the **Uniform System,** and it provides for black buoys with green or white lights on the starboard side and red buoys with red or white lights on the port side.

Most maritime countries using the lateral system have adopted one of these two systems, usually with small variations. It may be said that, *very generally,* European countries follow the Uniform System of 1936 and most other countries follow the system proposed in 1889. Special Publication No. 38 of the International Hydrographic Bureau, *Systems of Maritime Buoyage and Beaconage Adopted by Various Countries,* contains discussions and illustrations of the systems actually used by 39 maritime

countries, as well as the Uniform System. When actually piloting, *the navigator should in every case consult the latest nautical literature of the country in question.* The following is an abridgement of parts of IHB Special Publication No. 38:

United States System

The waters of the United States are marked by the lateral system of buoyage recommended by the International Marine Conference of 1889. As all channels do not lead from seaward, arbitrary assumptions are at times made in order that the system may be consistently applied. Along the sea coasts of the United States, the characteristics are based upon the assumption that proceeding "from seaward" constitutes a *clockwise* direction: a southerly direction along the Atlantic coast, a northerly and westerly direction along the Gulf coast, and a northerly direction along the Pacific coast. On the Great Lakes, a westerly and northerly direction is taken as being "from seaward" (except on Lake Michigan, where a southerly direction is used). On the Mississippi and Ohio Rivers and their tributaries, the characteristics of aids to navigation are determined as proceeding from sea toward the head of navigation. On the Intracoastal Waterway, proceeding in a generally southerly direction along the Atlantic coast and in a generally westerly direction along the Gulf coast is considered as proceeding "from seaward."

The continuation of the lateral system along the coasts in the order indicated refers only to the side of the vessel on which buoys are to be kept, as indicated by color, shape, and light, if any; there is no numerical continuity between coast buoys. In fairways and channels, however, buoys are numbered consecutively from seaward.

In the United States System, lighted buoys, bell buoys, whistle buoys, and combination buoys differ in shape (fig. 917) from the unlighted buoys shown in this appendix, but not in color or marking.

In the Mississippi River, the numbering and lighting of buoys differ from that shown under "Fairways and Channels."

Uniform System

As recommended by the League of Nations in 1936, a country uses the *Uniform Lateral System* or the *Uniform Cardinal System*, or both, according to its requirements or preference. When both are used, the transition from one to the other must be clearly indicated in appropriate publications, such as sailing directions, or by suitable buoyage marks.

Both the Uniform Lateral System and the Uniform Cardinal System employ **topmarks** as an additional means of identification. Unless otherwise stated in this appendix, a topmark is painted the darker of the colors used on the buoy. They are optional in every case except on wreck buoys in the Uniform Cardinal System. Topmarks are not used in the United States System.

In both the Uniform Lateral System and the Uniform Cardinal System, lighted buoys have the same shape as the unlighted buoys shown. This differs from the United States System, in which distinctively shaped buoys are used for lighted aids.

In both the Uniform Lateral System and the Uniform Cardinal System, a quick flashing light is regarded as a single flashing light.

The numbering or lettering of fairway and channel buoys is an optional feature of the Uniform Lateral System. In the United States System these buoys are always numbered, commencing from seaward.

UNITED STATES SYSTEM

Fairways and Channels

	PORT HAND	STARBOARD HAND
BUOY:		MARKING:	Odd numbers, commencing from seaward.	Even numbers, commencing from seaward.
LIGHTED BUOY:	*White* or *green*, flashing or occulting; or, when marking important turns, quick flashing.	*White* or *red*, flashing or occulting; or, when marking important turns, quick flashing.

Middle Grounds

	MAIN CHANNEL TO RIGHT	MAIN CHANNEL TO LEFT
BUOY:		MARKING:	May be lettered.	May be lettered.
LIGHTED BUOY:	*White* or *green*, interrupted quick flashing.	*White* or *red*, interrupted quick flashing.

Where channels are of equal importance, either of the above buoys is used, without regard to the uppermost band.

Mid Channel

BUOY: 

MARKING: May be lettered.

LIGHTED BUOY: *White*, short-long flashing.

Wrecks or Other Obstructions

	TO BE PASSED ON PORT HAND	TO BE PASSED ON STARBOARD HAND
BUOY:		MARKING:	Usually lettered "WR."	Usually lettered "WR."
LIGHTED BUOY:	*White* or *green*, quick flashing.	*White* or *red*, quick flashing.

Where wrecks or other obstructions may be passed on either hand, either Middle Ground *buoy is used, without regard to the uppermost band.*

UNITED STATES SYSTEM

Miscellaneous

SHAPE: Optional.

COLOR: **Quarantine**—*Yellow.*
Anchorage—*White.*
Fish Nets—*Black-and-white* horizontal bands.
Dredging—*White* with *green* top.
Seadromes—*Yellow-and-black* vertical stripes.
Special Purpose—*White-and-international orange* horizontal or vertical bands.

MARKING: May be lettered.

LIGHTED BUOY: Any color except *red* or *green*; fixed, occulting, or slow flashing.

UNIFORM LATERAL SYSTEM

Fairways and Channels

	PORT HAND	STARBOARD HAND
TOPMARK:		

"T"-shaped topmark not used at channel entrance.

Diamond-shaped top-mark not used at channel entrance.

BUOY:

In secondary channels only, yellow *may be substituted for* white *in checkered buoys.*

MARKING:

- Port Hand: Even numbers, commencing from seaward.
- Starboard Hand: Odd numbers, commencing from seaward.

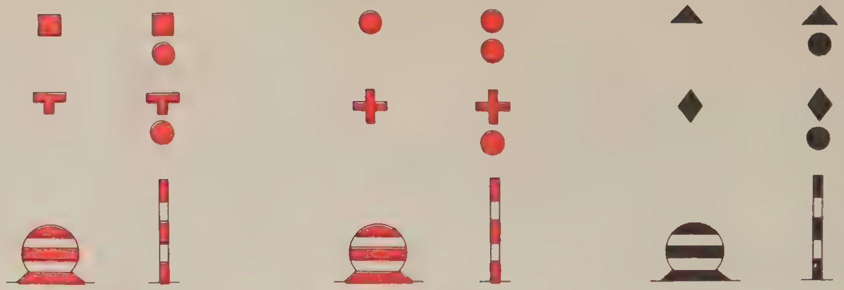
LIGHT:

- Port Hand: *Red,* single flashing or occulting or group flashing or occulting, with a number of flashes or occultations up to four; or *white,* group flashing or occulting (2 or 4); both *red and white* with above characteristics.
- Starboard Hand: *White,* single flashing or occulting, or group flashing or occulting (3); or *green,* of a different character from wreck markings; or both *white and green* with the above characteristics.

UNIFORM LATERAL SYSTEM

Middle Grounds

	MAIN CHANNEL TO RIGHT	CHANNELS OF EQUAL IMPORTANCE	MAIN CHANNEL TO LEFT
TOPMARK: *Bifurcation*			
Junction			
BUOY:			



LIGHT:	Distinctive where possible.	Distinctive where possible.	Distinctive where possible.

Mid Channel

TOPMARK: Shape optional, but not conical, cylindrical, or spherical.

BUOY: Shape optional, but not conical, cylindrical, or spherical.

COLOR: *Red-and-white* or *black-and-white* vertical stripes; topmark *red* or *black* to conform with buoy.

LIGHT: Different from neighboring lights.

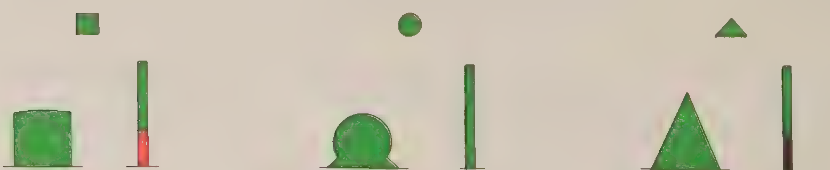
Marking of Wrecks

	TO BE PASSFD ON PORT HAND	TO BE PASSED ON EITHER HAND	TO BE PASSED ON STARBOARD HAND

By Buoys

TOPMARK:

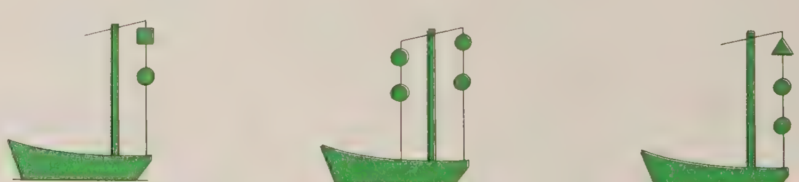
BUOY:



MARKING:	"W" in *white*.	"W" in *white*.	"W" in *white*.
LIGHT:	*Green*, group flashing (2).	*Green*, single occulting.	*Green*, group flashing (3).

By Vessels

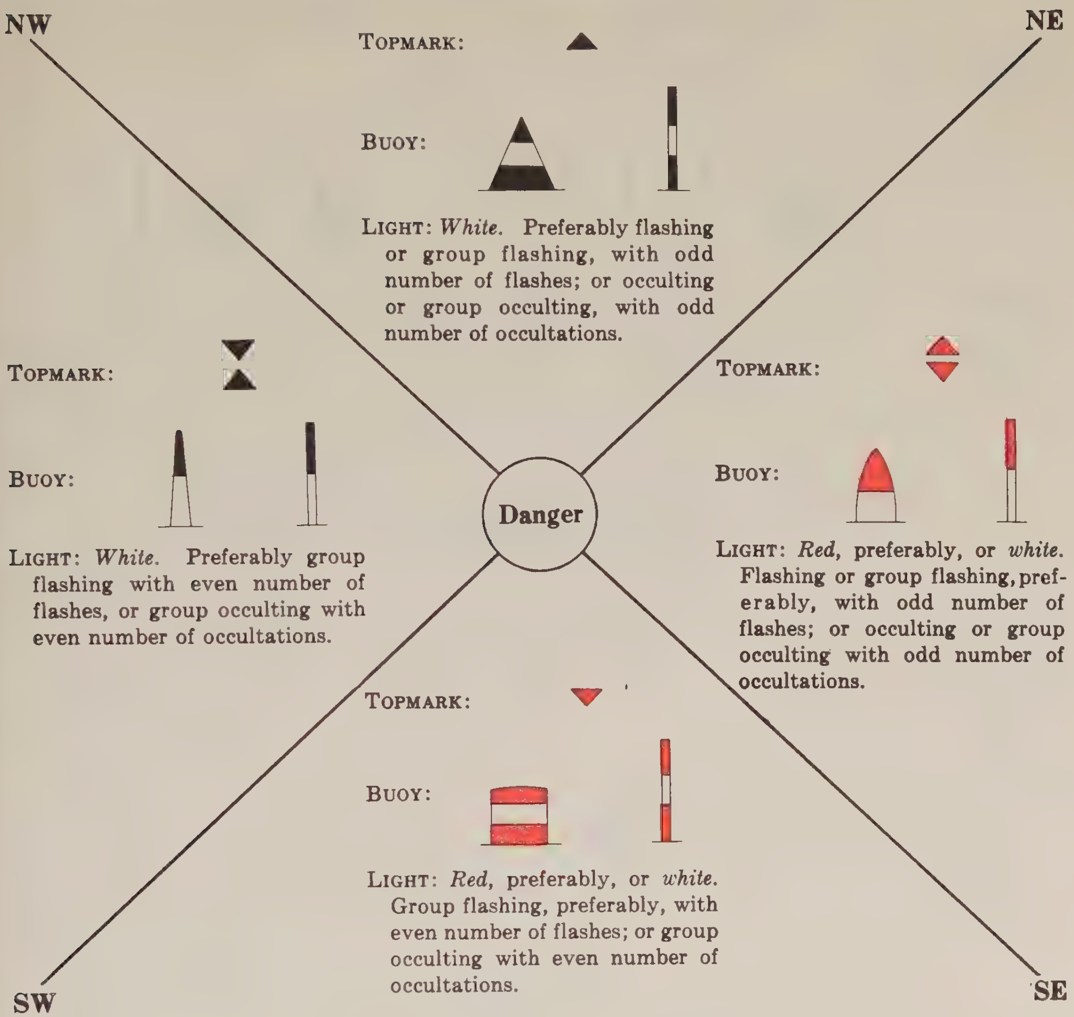
VESSEL:



MARKING:	"W" or "WRECK" in *white*.	"W" or "WRECK" in *white*.	"W" or "WRECK" in *white*.
LIGHT:	Fixed *green*, corresponding in number and arrangement to shapes displayed by day.		
BELL:	Two strokes at intervals of not more than 30 seconds.	Four strokes at intervals of not more than 30 seconds.	Three strokes at intervals of not more than 30 seconds.

UNIFORM CARDINAL SYSTEM

Danger Markings



Variations in Danger Markings

Note: The number of characteristic shapes employed for the buoy itself may be limited to two, the conical shape being employed in the northern and eastern quadrants and the cylindrical shape in the southern and western quadrants, as shown above.

Note: When spars only are used, it may be advantageous in the northern and eastern quadrants to reverse the positions of the dark colors, as shown above.

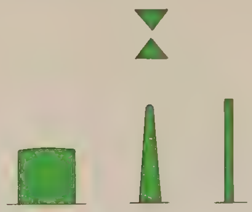
UNIFORM CARDINAL SYSTEM

Marking of Wrecks

Western Quadrant

Topmark:

Buoy:



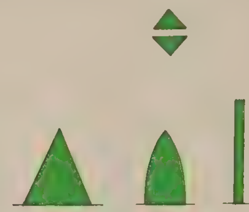
Marking: "W" in *white*, if possible.

Light: *Green*, quick flashing.

Eastern Quadrant

Topmark:

Buoy:



Marking: "W" in *white*, if possible.

Light: *Green*, interrupted quick flashing.

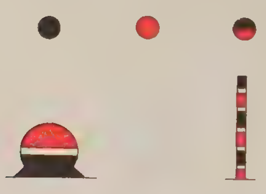
In the Uniform Cardinal System, wreck buoys are not used in the northern or southern quadrants.

UNIFORM SYSTEM—LATERAL AND CARDINAL
(Common To Both)

Isolated Dangers

Topmark:

Buoy:



Light: *White* or *red*, rhythmic.

Miscellaneous

Topmark: **Landfall**—Shape optional, but not misleading.
Transition—Shape optional, but not misleading.
Others—None.

Buoy: Shape optional, but not misleading.

Color: **Landfall**—*Black-and-white* or *red-and-white* vertical stripes.
Transition—*Red-and-white* or *black-and-white* spiral bands.
Quarantine—*Yellow*.
Outfall—*Yellow* above and *black* below.
Military Practice Area—*White*, with two *blue* stripes rising from the waterline and intersecting at right angles on top of the buoy, and, optionally, lettering in the national language indicating a danger area (*e.g.*, in English, "D.A.").

Light: **Landfall**—Rhythmic.
Outfall—Optional, with due regard to other lights in the area.
Others—None.

APPENDIX K

CHART SYMBOLS

(Extracts from Chart No. 1, September 1963)

GENERAL REMARKS

Chart No. 1 contains the standard symbols and abbreviations which have been approved for use of nautical charts published by the United States of America.

Symbols and abbreviations shown on Chart No. 1 apply to the regular nautical charts and may differ from those shown on certain reproductions and special charts.

Terms, symbols and abbreviations are numbered in accordance with a standard form approved by a Resolution of the Sixth International Hydrographic Conference, 1952.

Vertical figures indicate those items where the symbol and abbreviation are in accordance with the Resolutions of the International Hydrographic Conferences.

Slanting figures indicate those items where the symbol and/or abbreviation differ from the Resolutions of the Conferences, or for which Resolutions do not yet exist.

(*Those items which differ from the Resolutions are underlined.*)

Slanting letters in parentheses indicate that the items are in addition to those shown on the approved standard form.

Colors are optional for characterizing various features and areas on the charts.

Lettering styles and capitalization as used on Chart No. 1 are not always rigidly adhered to on the charts.

Longitudes are referred to the Meridian of Greenwich.

Scales are computed on the middle latitude of each chart, or on the middle latitude of a series of charts.

Buildings—A conspicuous feature on a building may be shown by a landmark symbol with descriptive note (See L–63 & I–n). Prominent buildings that are of assistance to the mariner are crosshatched (See I–3a, 5, 47 & 66).

Shoreline is the line of Mean High Water, except in marsh or mangrove areas, where the outer edge of vegetation (berm line) is used. A heavy line (A–9) is used to represent a firm shoreline. A light line (A–7) represents a berm line.

Heights of land and conspicuous objects are given in feet above Mean High Water, unless otherwise stated in the title of the chart.

Depth Contours and Soundings may be shown in meters on charts of foreign waters.

Visibility of a light is in nautical miles for an observer's eye 15 feet above water level.

Buoys and Beacons—On entering a channel from seaward, buoys on starboard side are red with even numbers, on port side black with odd numbers. Lights on buoys on starboard side of channel are red or white, on port side white or green. Mid-channel buoys have black-and-white vertical stripes. Junction or obstruction buoys, which may be passed on either side, have red-and-black horizontal bands. This system does not always apply to foreign waters. The dot of the buoy symbol, the small circle of the light vessel and mooring buoy symbols, and the center of the beacon symbol indicate their positions.

Improved channels are shown by limiting dashed lines, the depth, month, and the year of latest examination being placed adjacent to the channel, except when tabulated.

U.S. Coast Pilots, Sailing Directions, Light Lists, Radio Aids, and related publications furnish information required by the navigator that cannot be shown conveniently on the nautical chart.

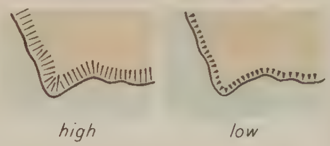
U.S. Nautical Chart Catalogs and Indexes list nautical charts, auxiliary maps, and related publications, and include general information (marginal notes, etc.) relative to the charts.

A glossary of foreign terms and abbreviations is generally given on the charts on which they are used, as well as in the Sailing Directions.

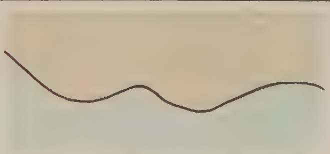
Charts already on issue will be brought into conformity as soon as opportunity affords.

A. The Coastline (Nature of the Coast)

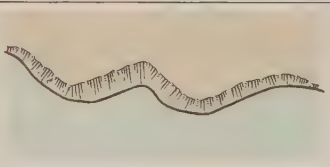
1 *Shoreline unsurveyed*



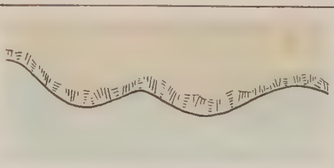
2 *Steep coast (Bluff)*



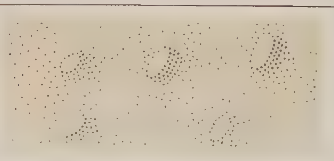
2a *Flat coast*



3 *Cliffy coast*

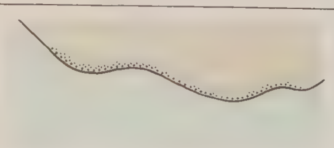


3a *Rocky coast*

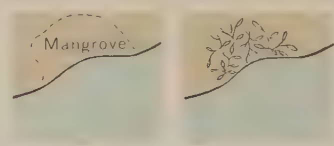


4 *Sandhills; Dunes*

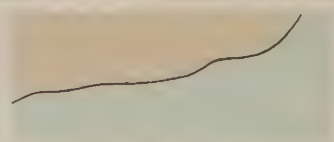
5 *Stony or Shingly shore*



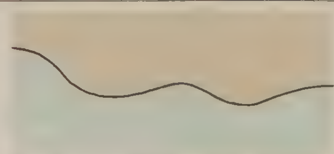
6 *Sandy shore*



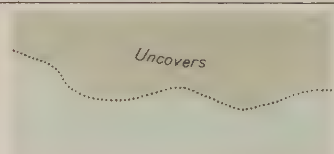
7 *Mangrove*



8 *Surveyed coastline*

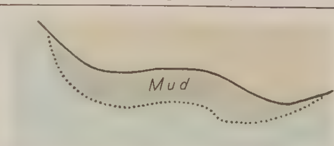


9 *High water line*

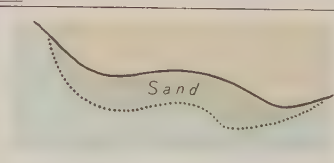


10 *Low water line*

11 **Foreshore**
(Strand in general)

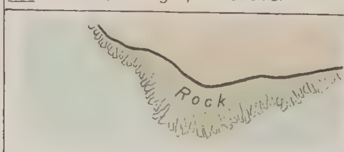


11a *Mud*



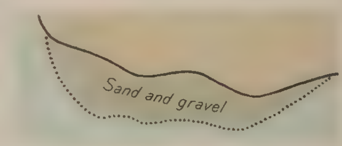
11b *Sand*

11c *Stones; Shingle; or Gravel*

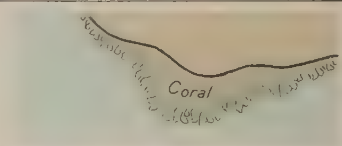


11d *Rock, uncovers at sounding datum (See A-11g)*

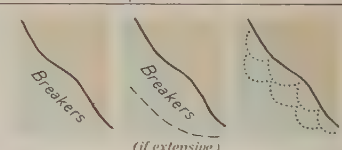
11e *Sand and mud*



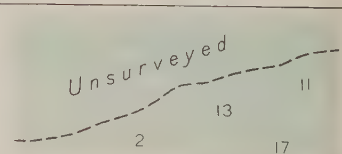
11f *Sand and gravel*



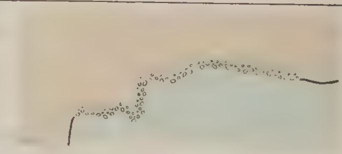
11g *Coral, uncovers at sounding datum (See O-10)*



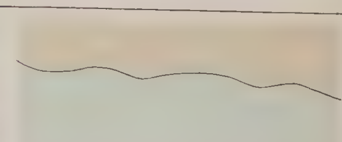
12 *Breakers along a shore (See O-25)*



14 *Limit of unsurveyed areas*



(Aa) *Rubble*

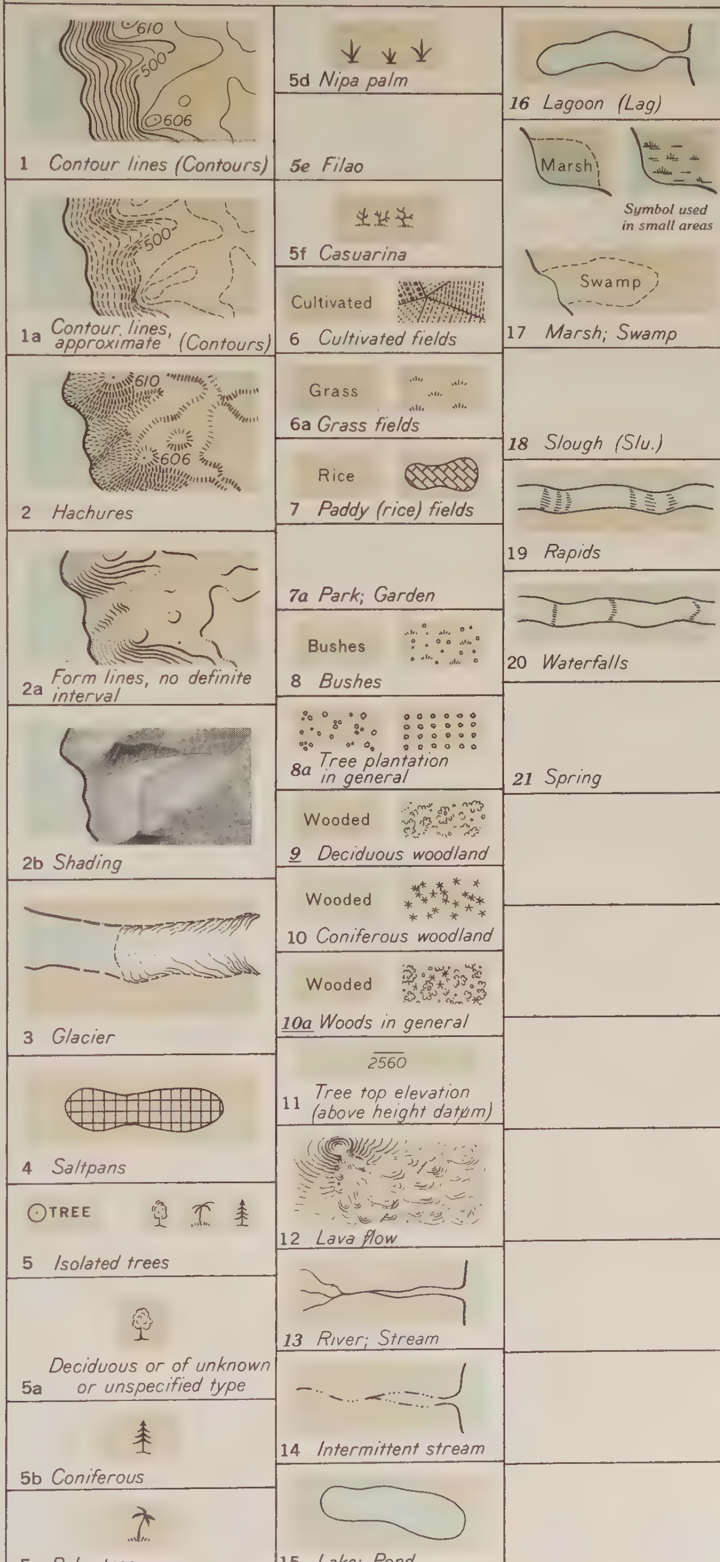


(Ab) *Shoreline from older surveys or small-scale charts*

B. Coast Features

1	G	Gulf
2	B	Bay
(Ba)	B	Bayou
3	Fd	Fjord
4	L	Loch; Lough; Lake
5	Cr	Creek
5a	C	Cove
6	In	Inlet
7	Str	Strait
8	Sd	Sound
9	Pass Thoro	Passage; Pass Thorofare
10	Chan	Channel
10a		Narrows
11	Entr	Entrance
12	Est	Estuary
12a		Delta
13	Mth	Mouth
14	Rd	Road; Roadstead
15	Anch	Anchorage
16	Hbr	Harbor
16a	Hn	Haven
17	P	Port
(Bb)	P	Pond
18	I	Island
19	It	Islet
20	Arch	Archipelago
21	Pen	Peninsula
22	C	Cape
23	Prom	Promontory
24	Hd	Head; Headland
25	Pt	Point
26	Mt	Mountain; Mount
27	Rge	Range
27a		Valley
28		Summit
29	Pk	Peak
30	Vol	Volcano
31		Hill
32	Bld	Boulder
33	Ldg	Landing
34		Table-land (Plateau)
35	Rk	Rock
36		Isolated rock
(Bc)	Str	Stream
(Bd)	R	River
(Be)	Slu	Slough
(Bf)	Lag	Lagoon
(Bg)	Apprs	Approaches
(Bh)	Rky	Rocky

C. The Land (Natural Features)



D. Control Points

1	△		*Triangulation point (station)*
2	⊙		*Fixed point (landmark) (See L-63)*
3	· 256		*Summit of height (Peak) (when not a landmark)*
(Da)			*Peak, accentuated by contours*
(Db)			*Peak, accentuated by hachures*
(Dc)			*Peak, elevation not determined*
(Dd)	⊙ 256		*Peak, when a landmark*
4	⊕	Obs Spot	*Observation spot*
5		BM	*Bench mark*
6	∘	See View	*View point*
7			*Datum point for grid of a plan*
8			*Graphical triangulation point*
9		Astro	*Astronomical*
10		Tri	*Triangulation*
(De)		C of E	*Corps of Engineers*
12			*Great trigonometrical survey station*
13			*Traverse station*
14		Bdy. Mon	*Boundary monument*
(Df)	◇		*International boundary monument*

E. Units

1	hr	*Hour*
2	m; min	*Minute (of time)*
3	sec	*Second (of time)*
4	m	*Meter*
4a	dm	*Decimeter*
4b	cm	*Centimeter*
4c	mm	*Millimeter*
4d	m^2	*Square meter*
4e	m^3	*Cubic meter*
5	km	*Kilometer*
6	in	*Inch*
7	ft	*Foot*
8	yd	*Yard*
9	fm	*Fathom*
10	cbl	*Cable length*
11	M	*Nautical mile*
12	kn	*Knot*
12a	t	*Ton*
12b	cd	*Candela (new candle)*
13	lat	*Latitude*
14	long	*Longitude*
15	pub	*Publication*
16	Ed	*Edition*
17	corr	*Correction*
18	alt	*Altitude*
19	ht; elev	*Height; Elevation*
20	°	*Degree*
21	′	*Minute (of arc)*
22	″	*Second (of arc)*

G. Ports and Harbors

No.	Symbol	Abbreviation	Description
1	⚓	*Anch*	*Anchorage (large vessels)*
2	⚓	*Anch*	*Anchorage (small vessels)*
3		*Hbr*	*Harbor*
4		*Hn*	*Haven*
5		*P*	*Port*
6		Bkw	*Breakwater*
6a			*Dike*
7			*Mole*
8			*Jetty (partly below MHW)*
8a			*Submerged jetty*
(Ga)			*Jetty (small scale)*
9		Pier	*Pier*
10			*Spit*
11			*Groin (partly below MHW)*
12	ANCHORAGE PROHIBITED	ANCH PROHIB	*Anchorage prohibited (See P-25)*
13	*Spoil Area*		*Spoil ground*
(Gb)	*Dumping Ground*		*Dumping ground*
(Gc)	80 85 83 *Disposal Area* *Depths from survey of June 1963* 95 90 98		*Disposal area*
14		Fsh stks	*Fisheries; Fishing stakes*
14a			*Fish trap; Fish weirs (actual shape charted)*
14b			*Duck blind*
15			*Tunny nets (See G-14a)*
15a	*Oys*	*Oys*	*Oyster bed*
16		Ldg	*Landing place*
17			*Watering place*
18		Whf	*Wharf*
19			*Quay*

No.	Symbol	Abbreviation	Description
20			*Berth*
20a	14		*Anchoring berth*
20b	3		*Berth number*
21	∘	Dol	*Dolphin*
22			*Bollard*
23			*Mooring ring*
24			*Crane*
25			*Landing stage*
25a			*Landing stairs*
26		Quar	*Quarantine*
27			*Lazaret*
28		Harbor Master	*Harbor master's office*
29		Cus Ho	*Customhouse*
30			*Fishing harbor*
31			*Winter harbor*
32			*Refuge harbor*
33		*B Hbr*	*Boat harbor*
34			*Stranding harbor (uncovers at LW)*
35			*Dock*
36			*Dry dock (actual shape on large-scale charts)*
37			*Floating dock (actual shape on large-scale charts)*
38			*Gridiron; Careening grid*
39			*Patent slip; Slipway; Marine railway*
39a		Ramp	*Ramp*
40	Lock		*Lock (point upstream) (See H-13)*
41			*Wet dock*
42			*Shipyard*
43			*Lumber yard*
44		Health Office	*Health officer's office*
45		*Hk*	*Hulk (actual shape on lrg. scale charts) (See O-11)*
46	PROHIBITED AREA	PROHIB AREA	*Prohibited area*
47			*Anchorage for seaplanes*
48			*Seaplane landing area*
49	*Under construction*		*Work in progress*
50			*Under construction*
(Gd)	*Subm ruins*		*Submerged ruins*

H. Topography (Artificial Features)

61	Vi	*Violet*
62		*Purple*
63	Bu	*Blue*
64	G	*Green*
65	Or	*Orange*
66	R	*Red*
67	W	*White*
67a	Am	*Amber*
68	*OBSC*	*Obscured light*
(Kf)	*Fog Det Lt*	*Fog detector light (See Nb)*

K. Lights (continued)

69		*Unwatched light*
70	Occas	*Occasional light*
71	Irreg	*Irregular light*
72	Prov	*Provisional light*
73	Temp	*Temporary light*
(Kg)	D; Destr	*Destroyed*
74	Exting	*Extinguished light*
75		*Faint light*
76		*Upper light*
77		*Lower light*
78		*Rear light*
79		*Front light*
80	Vert	*Vertical lights*
81	Hor	*Horizontal lights*
(Kh)	VB	*Vertical beam*
(Ki)	*RGE*	*Range*
(Kj)	Exper	*Experimental light*
(Kk)	TRLB	*Temporarily replaced by lighted buoy showing the same characteristics*
(Kl)	TRUB	*Temporarily replaced by unlighted buoy*
(Km)	TLB	*Temporary lighted buoy*
(Kn)	TUB	*Temporary unlighted buoy*

L. Buoys and Beacons (see General Remarks)

1		*Position of buoy*
2		*Light buoy*
3	*BELL*	*Bell buoy*
3a	*GONG*	*Gong buoy*
4	*WHIS*	*Whistle buoy*
5	*C*	*Can or Cylindrical buoy*
6	*N*	*Nun or Conical buoy*
7	*SP*	*Spherical buoy*
8	*S*	*Spar buoy*
8a	*P*	*Pillar buoy*
9		*Buoy with topmark (ball) (See L-70)*
10		*Barrel or Ton buoy*
(La)		*Color unknown*
(Lb)	*FLOAT*	*Float*
12	*FLOAT*	*Lightfloat*
13		*Outer or Landfall buoy*
14	*BW*	*Fairway buoy (BWVS)*
14a	*BW*	*Mid-channel buoy (BWVS)*
15	*R "2"*	*Starboard-hand buoy (entering from seaward)*
16	*"1"*	*Port-hand buoy (entering from seaward)*
17	*RB* *RB*	*Bifurcation buoy (RBHB)*
18	*RB* *RB*	*Junction buoy (RBHB)*
19	*RB* *RB*	*Isolated danger buoy (RBHB)*
20	*RB* *G*	*Wreck buoy (RBHB or G)*
20a	*RB* *G*	*Obstruction buoy (RBHB or G)*
21	*Tel*	*Telegraph-cable buoy*
22		*Mooring buoy (colors of mooring buoys never carried)*
22a		*Mooring*
22b	*Tel*	*Mooring buoy with telegraphic communications*
22c	*T*	*Mooring buoy with telephonic communications*
23		*Warping buoy*
24	*Y*	*Quarantine buoy*
25	*Explos Anch*	*Explosive anchorage buoy*
25a	*AERO*	*Aeronautical anchorage buoy*
26	*Deviation*	*Compass adjustment buoy*
27	*BW*	*Fish trap buoy (BWHB)*
27a		*Spoil ground buoy*
28		*Anchorage buoy (marks limits)*
29	*Priv maintd*	*Private buoy (maintained by private interests, use with caution)*

L. Buoys and Beacons (continued)

No.	Symbol	Abbreviation	Description
30			*Temporary buoy (See Kk, l, m, n)*
30a			*Winter buoy*
31		HB	*Horizontal stripes or bands*
32		VS	*Vertical stripes*
33		Chec	*Checkered*
(Lc)		Diag	*Diagonal buoy*
41		W	*White*
42		B	*Black*
43		R	*Red*
44		Y	*Yellow*
45		G	*Green*
46		Br	*Brown*
47		Gy	*Gray*
48		Bu	*Blue*
(Ld)		Am	*Amber*
(Le)		Or	*Orange*
51			*Floating beacon*
52	△RW Bn △W Bn ▲R Bn		*Fixed beacon (unlighted or daybeacon)*
	▲ Bn		*Black beacon*
	△ Bn		*Color unknown*
(Lf)	⊙ MARKER		*Private aid to navigation*
53		Bn	*Beacon, in general (See L-52)*
54			*Tower beacon*

No.	Symbol	Abbreviation	Description
55			*Cardinal marking system*
56	△ Deviation Bn		*Compass adjustment beacon*
57			*Topmarks (See L-9, 70)*
58			*Telegraph-cable (landing) beacon*
59	Piles		*Piles (See O-30, H-9)*
	⊥ ⊥		*Stakes*
	Stumps		*Stumps (See O-30)*
	⊥ ⊥		*Perches*
61	⊙ CAIRN ∘ Cairn		*Cairn*
62			*Painted patches*
63	⊙		*Landmark (conspicuous object) (See D-2)*
(Lg)	∘		*Landmark (position approximate)*
64		REF	*Reflector*
65	⊙ MARKER		*Range targets, markers*
(Lh)	W Or W Or		*Special-purpose buoys*
70			Note: *TOPMARKS on buoys and beacons may be shown on charts of foreign waters. The abbreviation for black is not shown adjacent to buoys or beacons.*
(Li)		Ra Ref	*Radar reflector (See M-13)*

M. Radio and Radar Stations

No.	Symbol	Description
1	°R. Sta	*Radio telegraph station*
2	°R. T	*Radio telephone station*
3	R. Bn	*Radiobeacon*
4	R. Bn	*Circular radiobeacon*
5	R.D	*Directional radiobeacon; Radio range*
6		*Rotating loop radiobeacon*
7	R.D.F	*Radio direction finding station*
(Ma)	TELEM ANT	*Telemetry antenna*
9	R. MAST	*Radio mast*
	R. TR	*Radio tower*
(Mb)	TV TR	*Television tower*
10	R. TR. (WBAL) 1090 Kc	*Radio broadcasting station (commercial)*
10a	°R. Sta	*Q.T.G. Radio station*
11	Ra	*Radar station*

No.	Symbol	Description
12	Racon	*Radar responder beacon*
13	Ra Ref	*Radar reflector (See Li)*
14	Ra (conspic)	*Radar conspicuous object*
14a		*Ramark*
15	D.F.S	*Distance finding station (synchronized signals)*
(Mc)	AERO R. Bn 302	*Aeronautical radiobeacon*
(Md)	AERO R. Rge 342	*Aeronautical radio range*
(Me)	Ra Ref Calibration Bn	*Radar calibration beacon*
(Mf)	CONSOL Bn 190 Kc MMF	*Consol (Consolan) station*
(Mg)	Loran Sta Venice	*Loran station (name)*
(Mh)	LORAN TR SPRING ISLAND	*Loran tower (name)*
(Mi)	10	*Radio calling-in point for traffic control*

N. Fog Signals

No.	Symbol	Description
1	Fog Sig	*Fog-signal station*
2		*Radio fog-signal station*
3	*GUN*	*Explosive fog signal*
4		*Submarine fog signal*
5	*SUB-BELL*	*Submarine fog bell (action of waves)*
6	*SUB-BELL*	*Submarine fog bell (mechanical)*
7	*SUB-OSC*	*Submarine oscillator*
8	*NAUTO*	*Nautophone*
9	*DIA*	*Diaphone*
10	*GUN*	*Fog gun*
11	*SIREN*	*Fog siren*

No.	Symbol	Description
12	*HORN*	*Fog trumpet*
13	*HORN*	*Fog horn*
14	*BELL*	*Fog bell*
15	*WHIS*	*Fog whistle*
16	*HORN*	*Reed horn*
17	*GONG*	*Fog gong*
18		*Submarine sound signal not connected to the shore (See N-5,6,7)*
18a		*Submarine sound signal connected to the shore (See N-5,6,7)*
(Na)	*HORN*	*Typhon*
(Nb)	*Fog Det Lt*	*Fog detector light (See Kf)*

O. Dangers

No.	Symbol	Description
1	(25)	Rock which does not cover (elevation above MHW) (See general remarks)
2	Uncov 2 ft; Uncov 2 ft; (2); (2)	Rock which covers and uncovers, with height in feet above chart (sounding) datum
3		Rock awash at the level of chart (sounding) datum
		When rock of O-2 or O-3 is considered a danger to navigation
4		Sunken rock with less than 6 feet of water over it (Same as O-26)
5		Sunken rock with between 6 and 33 ft. of water over it (Same as O-26)
5a	5 Rk	Shoal sounding on isolated rock (replaces symbol)
6		Sunken rock with more than 66 feet of water over it (Same as O-26)
6a	21 Rk; 21 Wk; 21 Obstr	Sunken danger with depth cleared by wire drag (in feet or fathoms)
7	Reef	Reef of unknown extent
8	Sub Vol	Submarine volcano
9	Discol Water	Discolored water
10	Coral; Co; Co; Co	Coral reef, detached (uncovers at sounding datum)
	Co 3; Reef Line	Coral or Rocky reef, covered at sounding datum (See A-lld, llg)
11		Wreck showing any portion of hull or superstructure above sounding datum
12	Masts	Wreck with only masts visible above sounding datum
13		Old symbols for wrecks
13a		Wreck always partially submerged
14		Sunken wreck which may be dangerous to surface navigation (See O-6a)
15	5½ Wk	Wreck over which depth is known
16		Sunken wreck, not dangerous to surface navigation
17	Foul	Foul ground
18	Tide Rips	Overfalls or Tide rips (Symbol used only in small areas)
19	Eddies	Eddies (Symbol used only in small areas)
20	Kelp	Kelp, Seaweed (Symbol used only in small areas)
21	Bk	Bank
22	Shl	Shoal
23	Rf	Reef (See A-lld, llg; O-10)
23a		Ridge
24	Le	Ledge
25		Breakers (See A-12)
26	+	Sunken rock (depth unknown)
		When rock is considered a danger to navigation
27	5½ Obstr	Obstruction
28		Wreck (See O-11 to 16)
29	Wreckage; Wks	Wreckage
29a		Wreck remains (dangerous only for anchoring)
30	Subm piles	Submerged piling (See H-9, L-59)
30a	Snags; Stumps	Snags; Submerged stumps (See L-59)
31		Lesser depth, possible
32	Uncov	Dries (See A-10; O-2, 10)
33	Cov	Covers (See O-2, 10)
34	Uncov	Uncovers (See A-10; O-2, 10)
	3 Rep (1958)	Reported (with date)
35	Eagle Rk (rep 1958)	Reported (with name and date)
36	Discol	Discolored (See O-9)
37		Isolated danger
38		Limiting danger line
39	rky	Limit of rocky area
41	PA	Position approximate
42	PD	Position doubtful
43	ED	Existence doubtful
44	P Pos	Position
45	D	Doubtful
(Oa)	Subm Crib; Crib (above water)	Crib
(Ob)	Platform (lighted) HORN	Offshore platform (unnamed)
(Oc)	Hazel (lighted) HORN	Offshore platform (named)

P. Various Limits, etc.

1		Leading line; Range line
2		Transit
3		In line with
4		Limit of sector
5		Channel, Course, Track recommended (marked by buoys or beacons)(See P-21)
(Pa)		Alternate course
6		Leader cable
7		Submarine cable (power, telegraph, telephone, etc.)
7a	Cable Area	Submarine cable area
8	Pipeline	Submarine pipeline
8a	Pipeline Area	Submarine pipeline area
9		Maritime limit in general
9a	RESTRICTED AREA	Limit of restricted area
10		Limit of fishing zone (fish trap areas)
11		Limit of dumping ground, spoil ground (See P-9, G-13)
12		Ancnorage limit
13		Limit of airport (See I-23, 24)
14		Limit of sovereignty (Territorial waters)
15		Customs boundary
16		International boundary (also State boundary)
17		Stream limit
18		Ice limit
19		Limit of tide
20		Limit of navigation
21		Course recommended (not marked by buoys or beacons)(See P-5)
22		District or province limit
23		Reservation line
24	COURSE 053°00′ TRUE MARKERS MARKERS	Measured distance
25	PROHIBITED AREA	Prohibited area (See G-12)

Q. Soundings

1	SD		Doubtful sounding
2	65		No bottom found
3			Out of position
4			Least depth in narrow channel
5	30 FEET APR 1958		Dredged channel (with controlling depth indicated)
6	24 FEET MAY 1958		Dredged area
7			Swept channel (See Q-9)
8	6		Drying or uncovering height in feet above chart (sounding) datum
9	17 119		Swept area, not adequately sounded (shown by green tint)
9a	29 23 3 22 8 30 8 21 7		Swept area adequately sounded (swept by wire drag to depth indicated)
10			Hair-line depths
10a	8_2	19	Figures for ordinary soundings
11	8_2	19	Soundings taken from foreign charts
12	8_2	19	Soundings taken from older surveys or smaller scale charts
13	8_2	19	Soundings taken by echo
14	8_2	19	Sloping figures (See Q-12)
15	8_2	19	Upright figures (See Q-10a)
16	(25)	(2)	Bracketed figures (See O-1, 2)
17	6		Underlined sounding figures (See Q-8)
18	3_2	6_1	Soundings expressed in fathoms and feet
(Qa)	6 5 2ft		Stream

R. Depth Contours and Tints (see General Remarks)

Feet	Fathoms		Feet	Fathoms	
0	0		300	50	
6	1		600	100	
12	2		1,200	200	
18	3		1,800	300	
24	4		2,400	400	
30	5		3,000	500	
36	6		6,000	1,000	
60	10		12,000	2,000	
120	20		18,000	3,000	
180	30		Or continuous lines, with values		5 (blue or black) 100
240	40				

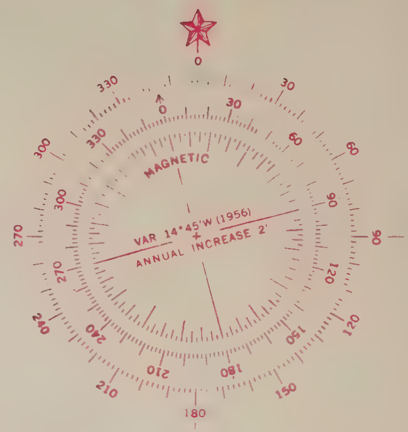
S. Quality of the Bottom

1		Ground	25	Ms	Mussels	50	spk	Speckled
2	S	Sand	26	Spg	Sponge	51	gty	Gritty
3	M	Mud; Muddy	27		Kelp	52		Decayed
4	Oz	Ooze	28	Wd	Seaweed	53	fly	Flinty
5	Ml	Marl		Grs	Grass	54	glac	Glacial
6	Cl	Clay	29		Seatangle	55		Tenacious
7	G	Gravel				56	wh	White
8	Sn	Shingle	31		Spicules	57	bk	Black
9	P	Pebbles	32	Fr	Foraminifera	58	vi	Violet
10	St	Stones	33	Gl	Globigerina	59	bu	Blue
11	Rk; rky	Rock; Rocky	34	Di	Diatoms	60	gn	Green
11a	Blds	Boulders	35	Rd	Radiolaria	61	yl	Yellow
12	Ck	Chalk	36	Pt	Pteropods	62	or	Orange
12a	Ca	Calcareous	37	Po	Polyzoa	63	rd	Red
13	Qz	Quartz	38		Cirripeda	64	br	Brown
13a		Schist	38a		Fucus	65	ch	Chocolate
14	Co	Coral	38b		Mattes	66	gy	Gray
(Sa)	Co Hd	Coral head	39	fne	Fine	67	lt	Light
15	Mds	Madrepores	40	crs	Coarse	68	dk	Dark
16	Vol	Volcanic	41	sft	Soft			
(Sb)	Vol Ash	Volcanic ash	42	hrd	Hard	70		Varied
17	La	Lava	43	stf	Stiff	71		Uneven
18	Pm	Pumice	44	sml	Small			
19	T	Tufa	45	lrg	Large			
20	Sc	Scoriae	46	stk	Sticky			
21	Cn	Cinders	47	brk	Broken			
22	Mn	Manganese	47a	grd	Ground	76		Fresh water springs in sea-bed
23	Sh	Shells	48		Rotten			
24	Oys	Oysters	49		Streaky			

T. Tides and Currents

1	HW	High water
1a	HHW	Higher high water
2	LW	Low water
(Ta)	LWD	Low water datum
2a	LLW	Lower low water
3	MTL	Mean tide level
4	MSL	Mean sea level
4a		Elevation of mean sea level above chart (sounding) datum
5		Chart datum (datum for sounding reduction)
6	Sp	Spring tide
7	Np	Neap tide
8	MHWS	Mean high water springs
8a	MHWN	Mean high water neaps
8b	MHHW	Mean higher high water
(Tb)	MHW	Mean high water
9	MLWS	Mean low water springs
9a	MLWN	Mean low water neaps
9b	MLLW	Mean lower low water
(Tc)	MLW	Mean low water
10	ISLW	Indian spring low water
11		High water full and change (vulgar establishment of the port)
12		Low water full and change
13		Mean establishment of the port
13a		Establishment of the port
14		Unit of height
15		Equinoctial
16		Quarter; Quadrature
17	Str.	Stream
18	2 kn	Current, general, with rate
19	2 kn	Flood stream (current) with rate
20	2 kn	Ebb stream (current) with rate
21	○ Tide gauge	Tide gauge; Tidepole; Automatic tide gauge
23	vel.	Velocity; Rate
24	kn.	Knots
25	ht.	Height
26		Tide
27		New moon
28		Full moon
29		Ordinary
30		Syzygy
31	fl.	Flood
32		Ebb
33	A B	Tidal stream diagram
34		Place for which tabulated tidal stream data are given
35		Range (of tide)
36		Phase lag
(Td)		Current diagram, with explanatory note

U. Compass



Compass Rose

The outer circle is in degrees with zero at true north. The inner circles are in points and degrees with the arrow indicating magnetic north.

1	N	North
2	E	East
3	S	South
4	W	West
5	NE	Northeast
6	SE	Southeast
7	SW	Southwest
8	NW	Northwest
9	N	Northern
10	E	Eastern
11	S	Southern
12	W	Western
21	brg	Bearing
22		True
23	mag	Magnetic
24	var	Variation
25		Annual change
25a		Annual change nil
26		Abnormal variation; Magnetic attraction
27	deg	Degrees (See E-20)
28	dev	Deviation

APPENDIX L

UNITS OF DEPTH MEASUREMENT ON CHARTS OF VARIOUS NATIONS

Nation	Unit of depth measurement	Equivalent in United States units	
		Feet	Fathoms
Argentina	Braza	6.000	1.000
Australia	Fathom	6.000	1.000
Belgium	Metre	3.281	0.547
Brazil	Metro	3.281	0.547
Canada	Fathom	6.000	1.000
Chile	Metro	3.281	0.547
Denmark	Favn	6.176	1.029
	Meter	3.281	0.547
Finland	Metre	3.281	0.547
France	Metre	3.281	0.547
Germany	Meter	3.281	0.547
Great Britain	Fathom	6.000	1.000
Greece	Metre (Metpa)	3.281	0.547
Italy	Metre	3.281	0.547
Japan	Metre	3.281	0.547
Netherlands	Vadem	5.905	0.984
	Meter	3.281	0.547
Norway	Favn	6.176	1.029
	Meter	3.281	0.547
Portugal	Metro	3.281	0.547
Russia (USSR)	Sazhen'	6.000	1.000
	Metre	3.281	0.547
Thailand	Metre	3.281	0.547
Spain	Metro	3.281	0.547
Sweden	Famn	5.844	0.974
	Meter	3.281	0.547
Turkey	Fathom (Kulac)	6.000	1.000
Uruguay	Metro	3.281	0.547
Yugoslavia	Metar	3.281	0.547

APPENDIX M

TIDAL DATUMS IN USE IN VARIOUS AREAS

Area	Datum	Area	Datum
Admiralty Islands	Lowest normal LW	Egypt (Mediterranean)	Mean LW springs
Alaska	Mean lower LW	El Salvador	Mean LW springs
Algeria	Lowest LW	Estonia	Mean sea level
Angola	Lowest normal LW	Ethiopia	Indian spring LW*
Argentina	Lowest normal LW	Finland	Mean sea level
Australia	Lowest normal LW**	France	Lowest LW
Azores	Lowest normal LW	French Guiana	Lowest LW
Bahama Islands	Mean lower LW springs	French Somaliland	Mean LW springs*
Belgium	Mean lower LW springs	Gabon	Lowest LW
Bermuda	Mean lower LW springs	Gambia	Mean lower LW springs
Bismarck Archipelago	Lowest normal LW	Germany (Baltic)	Mean sea level
Brazil	Indian spring LW*	Germany (North Sea)	Mean LW springs
British Guiana	Lowest normal LW	Ghana	Mean lower LW springs
British Honduras	Mean LW springs	Gilbert Islands	Mean LW springs
Bulgaria	Mean sea level	Great Britain	Mean LW springs*
Burma	Lowest normal LW	Greece	Mean LW springs*
Cambodia	Lowest LW	Greenland	Mean LW springs
Cameroon	Lowest LW	Guadeloupe	Lowest LW
Canada	Lowest normal LW	Guam	Mean lower LW
Canal Zone (Atlantic)	Mean LW	Guatemala	Mean LW springs
Canal Zone (Pacific)	Mean LW springs	Guinea	Lowest LW
Canary Islands	Lowest normal LW	Haiti	Mean LW
Caroline Islands	Lowest normal LW	Hawaiian Islands	Mean lower LW
Chile	Lowest normal LW	Honduras (Atlantic)	Mean lower LW
China	Lowest normal LW	Honduras (Pacific)	Mean LW springs
Colombia (Atlantic)	Mean LW	Iceland	Mean LW springs
Colombia (Pacific)	Mean LW springs	India	Indian spring LW*
Congo	Lowest LW	Indonesia	Lowest normal LW
Costa Rica (Atlantic)	Mean LW	Iran	Indian spring LW
Costa Rica (Pacific)	Mean LW springs	Iraq	Indian spring LW
Cuba	Mean LW	Israel	Mean LW springs
Denmark (Baltic)	Mean sea level	Italy	Mean LW springs
Denmark (North Sea)	Mean LW springs	Ivory Coast	Lowest LW
Dominican Republic	Mean LW	Jamaica	Mean lower LW springs
Ecuador	Mean LW springs	Japan	Indian spring LW
Egypt (Red Sea)	Indian spring LW*	Kenya	Indian spring LW

*The chart datum is somewhat lower than the datum indicated.

**A chart datum approximating mean LW springs or Indian spring LW is used for a number of places on the north and northwest coasts of Australia.

APPENDIX M

TIDAL DATUMS IN USE IN VARIOUS AREAS

Area	Datum	Area	Datum
Korea	Indian spring LW	Saudi Arabia	Indian spring LW*
Latvia	Mean sea level	Senegal	Lowest LW
Liberia	Mean lower LW springs	Sierra Leone	Mean lower LW springs
Libya	Mean LW springs	Solomon Islands	Lowest normal LW
Lithuania	Mean sea level	Somali Republic	Mean LW springs*
Loyalty Islands	Lowest normal LW	South Africa	Mean LW springs
Madagascar	Lowest LW	South-West Africa	Mean LW springs*
Madeira Islands	Lowest normal LW	Spain	Lowest normal LW
Malaya	Lowest normal LW	Spanish Sahara	Lowest normal LW
Mariana Islands	Lowest normal LW**	Sudan	Indian spring LW*
Marshall Islands	Lowest normal LW	Surinam	Mean lower LW springs
Martinique	Lowest LW	Sweden	Mean sea level
Mauritania	Lowest LW	Syria	Mean LW springs*
Mexico (part of Atlantic)	Mean LW	Tanganyika	Mean LW springs
Mexico (Pacific and part of Atlantic)	Mean lower LW	Thailand	Lowest normal LW
Morocco	Lowest LW	Tinian	Mean lower LW
Mozambique	Lowest LW	Togo	Lowest LW
Netherlands	Mean lower LW springs	Trinidad	Mean lower LW springs
New Caledonia	Lowest LW	Tuamoto Archipelago	Mean LW springs
New Hebrides	Lowest normal LW	Tunisia	Lowest LW
New Zealand	Lowest normal LW	Turkey (Black Sea)	Mean sea level
Nicaragua	Mean LW springs	Turkey (Mediterranean)	Mean LW springs
Nigeria	Mean LW springs	United Arab Republic (Egypt) (Mediterranean)	Mean LW springs
Norway	Equatorial spring LW	United Arab Republic (Egypt) (Red Sea)	Indian spring LW*
Pakistan	Lowest normal LW	USA (Atlantic)	Mean LW
Panama (Atlantic)	Mean LW	USA (Pacific)	Mean lower LW
Panama (Pacific)	Mean LW springs	USSR (Baltic and Black Sea)	Mean sea level
Papua	Lowest LW	USSR (Arctic and Pacific)	Lowest normal LW
Peru	Mean LW springs	Uruguay	Lowest normal LW
Philippines	Mean lower LW	Venezuela	Mean LW springs
Poland	Mean sea level	Vietnam	Lowest LW
Portugal	Lowest normal LW	Virgin Islands	Mean LW
Portuguese Guinea	Lowest normal LW	Yugoslavia	Mean lower LW springs
Puerto Rico	Mean LW		
Rio Muni	Lowest normal LW		
Rumania	Mean sea level		
Saipan	Mean lower LW		
Samoa	Mean LW springs		

*The chart datum is somewhat lower than the datum indicated.
**At Guam, Saipan, and Tinian the chart datum is mean lower LW.

APPENDIX N

SOURCES OF CHARTS AND PUBLICATIONS

Certain types of charts and publications, listed below, can be purchased from the places indicated. Many of the publications listed are also available from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402.

Orders for charts or publications, when addressed to Government agencies, should be accompanied by a check or post office money order made payable to the Treasurer of the United States. Postage stamps are not accepted, and cash is sent at the sender's risk of loss.

Government agencies make no charge for postage to addresses in the United States and possessions, and none to Canada, Cuba, Mexico, and Panama if the total weight of the shipment does not exceed four pounds. In all other cases, postage is required at the rates for printed matter. Remittance should accompany the order.

Orders for charts and publications should be as specific as possible, citing the numbers assigned by the publishing agency as identification of the items desired. To facilitate selection, the U.S. Navy Hydrographic Office, Washington, D.C. 20390 and U.S. Coast and Geodetic Survey, Washington, D.C. 20230, distribute free of charge, catalogs of salable material. More detailed information on U.S. Navy Hydrographic Office nautical charts and publications is given in Pub. No. 1–N, Introduction Part I. Aeronautical charts and publications are listed in the *Catalog of U.S. Navy Aeronautical Charts and Related Publications*, the *Coast and Geodetic Survey Catalog of Aeronautical Charts and Related Publications* and the *DOD Catalog of Aeronautical Charts and Flight Information Publications*. The DOD catalog is available only to military users.

Nautical Charts

Coasts of the United States and its territories and possessions.	U.S. Coast and Geodetic Survey and sales agents.
Mississippi River from the Head of Passes to Cairo, Ill.	Mississippi River Commission, Vicksburg, Miss.
Illinois waterway system (Great Lakes to Gulf of Mexico).	District Engineer, Chicago District, Chicago, Ill.
Various United States rivers.	District Engineer Offices.
Great Lakes, Lake Champlain, and the St. Lawrence River above St. Regis and Cornwall, Canada.	U.S. Lake Survey, Detroit, Mich., and District Engineer, Buffalo District, Buffalo, N.Y.
New York State canals.	U.S. Lake Survey, Detroit, Mich.; Superintendent of Public Works, Albany, N.Y.; and District Engineer, Buffalo District, Buffalo, N.Y.
Coasts of foreign countries.	U.S. Navy Hydrographic Office sales agents.

Oceanographic Charts and Publications

Tide and tidal current tables.	U.S. Coast and Geodetic Survey and sales agents.
Tidal current charts, certain United States harbors.	U.S. Coast and Geodetic Survey and sales agents.
Current charts of the oceans.	U.S. Navy Hydrographic Office sales agents.
Pilot charts.	U.S. Navy Hydrographic Office sales agents.
Bottom sediment charts.	U.S. Navy Hydrographic Office sales agents.
Surface temperature charts.	U.S. Navy Hydrographic Office sales agents.
Sea and swell charts.	U.S. Navy Hydrographic Office sales agents.
Water temperature and density tables.	U.S. Coast and Geodetic Survey and sales agents.
Oceanographic Atlas of the Polar Seas (Pub. No. 705).	U.S. Navy Hydrographic Office sales agents.
Sonic Soundings (H.O. Pub. No. 606–b).	U.S. Navy Hydrographic Office sales agents.
Bathythermograph Observations (H.O. Pub. No. 606–c).	U.S. Navy Hydrographic Office sales agents.
Ice Observations (H.O. Pub. No. 606–d).	U.S. Navy Hydrographic Office sales agents.
Sea and Swell Observations (H.O. Pub. No. 606–e).	U.S. Navy Hydrographic Office sales agents.
Miscellaneous oceanographic publications.	U.S. Navy Hydrographic Office sales agents and U.S. Coast and Geodetic Survey and sales agents.

Electronic Navigation

Loran charts.	U.S. Navy Hydrographic Office sales agents; U.S. Coast and Geodetic Survey and sales agents; and U.S. Air Force Aeronautical Chart and Information Center.
Loran tables (H.O. Pub. No. 221, various rates).	U.S. Navy Hydrographic Office sales agents.
Radio Navigational Aids (H.O. Pub. No. 117).	U.S. Navy Hydrographic Office sales agents.
Radio Weather Aids (H.O. Pub. No. 118).	U.S. Navy Hydrographic Office sales agents.
Weather Station Index (H.O. Pub. No. 119).	U.S. Navy Hydrographic Office sales agents.
Radio circulars giving schedules, frequencies, and data included in weather broadcasts.	Chief, U.S. Weather Bureau. (Also in H.O. Pub. No. 117).
International Code of Signals, Vol. II, radio (H.O. Pub. No. 104).	U.S. Navy Hydrographic Office sales agents.
Federal Communications Commission Rules and Regulations, Vol. IV, July 1964.	Superintendent of Documents.
Communications Act of 1934, Revised 1960.	Superintendent of Documents.
International Convention for the Safety of Life at Sea, 1960.	Intergovernmental Maritime Consultative Organization, London, England.
International Publications:	International Telecommunication Union, Geneva, Switzerland.
List of Frequencies.	
List of Coast Stations.	
List of Ship Stations.	
List of Broadcasting Stations.	
List of Radio Determination and Special Service Stations.	
List of Call Signs of Stations Used by the Maritime Mobile Service.	
List of Fixed Stations Operating International Circuits.	
Radio Aids to Maritime Navigation and Hydrography. (IHB Special Pub. No. 39).	International Hydrographic Bureau, Monaco.

Navigational Publications

Coast pilots (sailing directions), coasts of the United States and its territories and possessions.	U.S. Coast and Geodetic Survey and sales agents.
Sailing directions (coast pilots), foreign coasts.	U.S. Navy Hydrographic Office sales agents.
Light lists, United States waters.	Published by U.S. Coast Guard, distributed by Superintendent of Documents and sales agents.
Light lists, foreign coasts.	U.S. Navy Hydrographic Office sales agents.
Navigational tables:	U.S. Navy Hydrographic Office sales agents.
Table of Distances Between Ports (H.O. Pub. No. 151).	
Tables of Computed Altitude and Azimuth (H.O. Pub. No. 214, nine vols.).	
Sight Reduction Tables for Air Navigation (H.O. Pub. No. 249, three vols.).	
Various sight reduction tables (H.O. Pubs. Nos. 208, 211, 218).	
Azimuths of the Sun (H.O. Pub. No. 260).	
Azimuths of Celestial Bodies (H.O. Pub. No. 261).	
Distances Between United States Ports.	U.S. Coast and Geodetic Survey and sales agents.
Almanacs:	Published by U.S. Naval Observatory, distributed by Superintendent of Documents and sales agents.
The Air Almanac.	
The American Ephemeris and Nautical Almanac.	
The Nautical Almanac.	

Periodical Publications

Notice to Mariners.	U.S. Navy Hydrographic Office and branches.
Daily Memorandum.	U.S. Navy Hydrographic Office and branches.

Miscellaneous

Isomagnetic charts.	U.S. Navy Hydrographic Office sales agents.
Magnetic variation charts of the United States, Caribbean, and Alaska.	U.S. Coast and Geodetic Survey and sales agents.
Great-circle charts.	U.S. Navy Hydrographic Office sales agents.
Charts of polar regions.	U.S. Navy Hydrographic Office sales agents and U.S. Air Force Aeronautical Chart and Information Center.
Aeronautical charts, United States.	U.S. Coast and Geodetic Survey and sales agents.
Aeronautical charts, world coverage.	U.S. Hydrographic Office sales agents and U.S. Air Force Aeronautical Chart and Information Center.
Aeronautical publications.	U.S. Navy Hydrographic Office sales agents and Federal Aviation Agency.
Plotting charts and plotting sheets.	U.S. Navy Hydrographic Office sales agents.
Special charts.	U.S. Navy Hydrographic Office sales agents and U.S. Coast and Geodetic Survey and sales agents.
International Code of Signals, Vol. I, visual (H.O. Pub. No. 103).	U.S. Navy Hydrographic Office sales agents.
Merchant Marine House Flags and Stack Insignia (H.O. Pub. No. 100).	U.S. Navy Hydrographic Office sales agents.
Navigational Observations (H.O. Pub. No. 606–a).	U.S. Navy Hydrographic Office sales agents.
Shipboard Wind Plotter.	U.S. Weather Bureau.
Weather maps and reports.	U.S. Weather Bureau.
Mariners Weather Log.	Published by U.S. Weather Bureau, distributed by Superintendent of Documents.
World Port Index (H.O. Pub. No. 150).	U.S. Navy Hydrographic Office sales agents.
Eskimo Place Names and Aids to Conversation (H.O. Misc. 10578).	U.S. Navy Hydrographic Office sales agents.
Star Finder and Identifier (H.O. 2102–D).	U.S. Navy Hydrographic Office sales agents.
Rules of the Road—International—Inland (CG–169).	Published by U.S. Coast Guard, distributed by Superintendent of Documents and sales agents.
Rules of the Road—Great Lakes (CG–172).	Published by U.S. Coast Guard, distributed by Superintendent of Documents and sales agents.
Rules of the Road—Western Rivers (CG–184).	Published by U.S. Coast Guard, distributed by Superintendent of Documents and sales agents.
Systems of Maritime Buoyage and Beaconage Adopted by Various Countries. (IHB Special Pub. No. 38).	International Hydrographic Bureau, Monaco.
Aids to Marine Navigation of the United States (CG–193).	Published by U.S. Coast Guard, distributed by Superintendent of Documents and sales agents.
Radar Plotting Manual (H.O. Pub. No. 257).	U.S. Navy Hydrographic Office sales agents.
Maneuvering Board Manual (H.O. Pub. No. 217).	U.S. Navy Hydrographic Office sales agents.
Navigation Dictionary (H.O. Pub. No. 220).	U.S. Navy Hydrographic Office sales agents.
Handbook of Magnetic Compass Adjustment and Compensation (H.O. Pub. No. 226).	U.S. Navy Hydrographic Office sales agents.
Laws Governing Marine Inspection (CG–227).	Published by U.S. Coast Guard, distributed by Superintendent of Documents and sales agents.
Instrument instruction pamphlets.	Manufacturer of equipment.
Great Lakes Pilot.	U.S. Lake Survey, Detroit, Michigan.

APPENDIX O

MATHEMATICS

Arithmetic

O1. Definitions.—**Arithmetic** is that branch of mathematics dealing with computation by numbers. The principal processes involved are addition, subtraction, multiplication, and division. A number consisting of a single symbol (1, 2, 3, etc.) is a **digit.** Any number that can be stated or indicated, however large or small, is called a **finite** number; one too large to be stated or indicated is called an **infinite** number; and one too small to be stated or indicated is called an **infinitesimal** number.

The **sign** of a number is the indication of whether it is positive (+) or negative (−). This may sometimes be indicated in another way. Thus, latitude is usually indicated as *north* (N) or *south* (S), but if north is considered positive, south is then negative with respect to north. In navigation, the north or south designation of latitude and declination is often called the "name" of the latitude or declination. A **positive number** is one having a positive sign (+); a **negative number** is one having a negative sign (−). The **absolute value** of a number is that number without regard to sign. Thus, the absolute value of both (+) 8 and (−) 8 is 8. Generally, a number without a sign can be considered positive.

O2. Expressing numbers.—In navigation, fractions are usually expressed as decimals. Thus, $\frac{1}{4}$ is expressed as 0.25 and $\frac{1}{3}$ as 0.33. To determine the decimal equivalent of a fraction, divide the **numerator** (the number above the line) by the **denominator** (the number below the line). When a decimal is less than 1, as in the examples above, it is good practice to show the zero at the left of the decimal point (0.25, not .25).

A number should not be expressed to a greater precision than justified. The precision of a decimal is indicated by the number of digits shown to the right of the decimal point. Thus, the expression "14 miles" indicates a precision to the nearest whole mile, or any value between 13.5 and 14.5 miles. The expression "14.0 miles" indicates a precision of a tenth of a mile, or any value between 13.95 and 14.05 miles.

In a number without a decimal there is sometimes doubt as to the degree of precision indicated. For example, the number 186,000 may indicate a precision to three, four, five, or six places. This ambiguity is sometimes avoided by expressing numbers as powers of 10 (art. O8). Thus, 18.6×10^4 ($18.6 \times 10{,}000$) indicates a precision to the nearest thousand (three places), 18.60×10^4 to the nearest hundred (four places), 18.600×10^4 to the nearest ten (five places), and 18.6000×10^4 to the nearest unit (six places). The position of the decimal is not important if the correct power of 10 is given. For example, 18.6×10^4 is the same as 1.86×10^5, 186×10^3, etc.

The small number above and to the right of 10 (the **exponent**) indicates the number of places the decimal point is to be moved to the *right.* If the exponent is negative, it indicates a reciprocal, and the decimal point is moved to the *left.* Thus, $1.86 \times 10^{-6} = 0.00000186$. This system is sometimes used to avoid long numbers.

Another way of indicating degree of precision is to state the number of **significant digits.** These are the digits in a number, excluding zeros at the left and sometimes those at the right. Thus, 1,325, 1,001, 1.408, 0.00005926, 625.0, and 0.04000 have four significant digits each. But in the number 312,600 there may be four, five, or six

significant digits. Any doubt may be removed by expressing the number times a power of 10, as explained above.

If there are no more significant digits, regardless of how far a computation is carried, this may be indicated by use of the word "exactly." Thus, $12 \div 4 = 3$ exactly, and one nautical mile=1,852 meters exactly; but $12 \div 7 = 1.7$ approximately, the word "approximately" indicating that additional decimal places might be computed. Another way of indicating an approximate relationship is by placing a positive or negative sign after the number. Thus, $12 \div 7 = 1.7+$, and $11 \div 7 = 1.6-$. This system has the advantage of showing whether the approximation is too great or too small.

In any arithmetical computation the answer is no more accurate than the least precise value used. Thus, if it is desired to add 16.4 and 1.88, the answer might be given as 18.28, but since the first term might be anything from 16.35 to 16.45, the answer is anything from 18.23 to 18.33. Hence, to retain the second decimal place in the answer is to give a false indication of accuracy, for the number 18.28 indicates a value between 18.275 and 18.285. However, additional places are sometimes retained until the end of a computation to avoid an accumulation of small errors due to rounding off (art. O4). In marine navigation it is customary to give most values to a precision of 0.1, even though some uncertainty may exist as to the accuracy of the last place. Examples are the dip and refraction corrections of sextant altitudes (arts. 1606, 1613).

In general, a value obtained by interpolation in a table should not be expressed to more decimal places than given in the table.

O3. Precision and accuracy.—The word "precision" as used above is not the same as "accuracy," although the two are sometimes confused. A quantity may be expressed to a greater precision than is justified by the accuracy of the information from which the quantity is derived. For instance, if a ship steams one mile in 3^m21^s, its speed is $60^m \div 3^m21^s = 60 \div 3.35 = 17.910447761194$ knots, approximately. The division can be carried to as many places as desired, but if the time is measured only to the nearest second, the speed is accurate only to one decimal place in this example, because an error of 0.5 second introduces an error of more than 0.05 knot in the speed. Hence, the additional places are meaningless and possibly misleading, unless more accurate time is available. In general, it is not good practice to state a quantity to greater precision than justified by its accuracy. However, in marine navigation the accuracy of information is often unknown, and it is customary to give positions to a precision of $0'.1$ of latitude and longitude, although they *may* not be accurate even to the nearest whole minute.

The **absolute precision** of a number is indicated by its number of decimal places; its **relative precision** by its number of significant digits. Although this is an indication of precision, it may also be a measure of accuracy, and the expressions **absolute accuracy** and **relative accuracy** used. However, the term "accuracy" should not be used when "precision" only is intended. Thus, the values 186,000 and 0.00000186 may each have three significant digits, or "be correct to three digits," although the first value may be accurate ("absolute accuracy") only to the nearest 1,000, and the second to the nearest 0.00000001. If the numbers are accurate to the number of significant digits shown, each has an error ("relative accuracy") of less than "one part in 186."

Unless all numbers are exact, doubt exists as to the accuracy of the last digit in a computation. Thus, $12.3+9.4+4.6=26.3$. But if the three terms to be added have been rounded off from 12.26, 9.38, and 4.57, the correct answer is 26.2, obtained by rounding off the answer of 26.21 found by retaining the second decimal place until the end. It is good practice to work with one more place than needed in the answer,

when the information is available. In computations involving a large number of terms, or if great accuracy is desired, it is sometimes advisable to retain two or more additional places until the end.

O4. Rounding off.—In rounding off numbers to the number of places desired, one should take the nearest value. Thus, the number 6.5049 is rounded to 6.505, 6.50, 6.5, or 7, depending upon the number of places desired. If the number to be rounded off ends in 5, the nearer *even* number is taken. Thus, 1.55 and 1.65 are both rounded to 1.6. Likewise, 12.750 is rounded to 12.8 if only one decimal place is desired. However, 12.749 is rounded to 12.7. That is, 12.749 is not first rounded to 12.75 and then to 12.8, but the entire number is rounded in one operation. When a number ends in 5, the computation can sometimes be carried to additional places to determine whether the correct value is more or less than 5.

O5. Reciprocals.—The reciprocal of a number is 1 divided by that number. The reciprocal of a fraction is obtained by interchanging the numerator and denominator. Thus, the reciprocal of $\frac{3}{5}$ is $\frac{5}{3}$. A whole number may be considered a fraction with 1 as the denominator. Thus, 54 is the same as $\frac{54}{1}$, and its reciprocal is $\frac{1}{54}$. Division by a number produces the same result as multiplying by its reciprocal, or vice versa. Thus, $12 \div 2 = 12 \times \frac{1}{2} = 6$, and $12 \times 2 = 12 \div \frac{1}{2} = 24$.

O6. Addition.—When two or more numbers are to be added, it is generally most convenient to write them in a column, with the decimal points in line. Thus, if 31.2, 0.8874, and 168.14 are to be added, this may be indicated by means of the addition sign (+): $31.2 + 0.8874 + 168.14 = 200.2$. But the addition can be performed more conveniently by arranging the numbers as follows:

$$\begin{array}{r@{.}l} 31 & 2 \\ 0 & 8874 \\ 168 & 14 \\ \hline 200 & 2. \end{array}$$

The answer is given only to the first decimal place, because the answer is no more accurate than the least precise number among those to be added, as indicated previously. Often it is preferable to state all numbers in a problem to the same precision before starting the addition, although this may introduce a small error, as indicated in article O3:

$$\begin{array}{r@{.}l} 31 & 2 \\ 0 & 9 \\ 168 & 1 \\ \hline 200 & 2. \end{array}$$

If there are no decimals, the last digit to the right is aligned:

$$\begin{array}{r} 166 \\ 2 \\ 96{,}758 \\ \hline 96{,}926. \end{array}$$

Numbers to be added should be given to the same absolute accuracy, when available, to avoid a false impression of accuracy in the result. Consider the following:

$$\begin{array}{r} 186{,}000 \\ 71{,}832 \\ 9{,}614 \\ 728 \\ \hline 268{,}174. \end{array}$$

The answer would imply an accuracy to six places. If the first number given is accurate to only three places, or to the nearest 1,000, the answer is not more accurate, and hence the answer should be given as 268,000. Approximately the same answer would be obtained by rounding off at the start:

$$\begin{array}{r} 186{,}000 \\ 72{,}000 \\ 10{,}000 \\ \underline{1{,}000} \\ 269{,}000. \end{array}$$

If numbers are **added arithmetically,** their absolute values are added without regard to signs; but if they are **added algebraically,** due regard is given to signs. If two numbers to be added algebraically have the same sign, their absolute values are added and given their common sign. If two numbers to be added algebraically have unlike signs, the smaller absolute value is subtracted from the larger, and the sign of the value having the larger absolute value is given to the result. Thus, if $+8$ and -7 are added arithmetically, the answer is 15, but if they are added algebraically, the answer is $+1$.

An answer obtained by addition is called a **sum.**

O7. Subtraction is the inverse of addition. Stated differently, the *addition* of a *negative* number is the same as the *subtraction* of a *positive* number. That is, if a number is to be subtracted from another, the sign (+ or −) of the **subtrahend** (the number to be subtracted) is reversed and the result added algebraically to the **minuend** (the number from which the subtrahend is to be subtracted). Thus, $6-4=2$. This may be written $+6-(+4)=+2$, which yields the same result as $+6+(-4)$. For solution, larger numbers are often conveniently arranged in a column with decimal points in a vertical column, as in addition. Thus, $3{,}728.41-1{,}861.16$ may be written

$$\begin{array}{ll} (+)3{,}728.41 & \\ (+)\underline{1{,}861.16} & \text{(subtract)} \\ (+)1{,}867.25 & \end{array}$$

This is the same as

$$\begin{array}{ll} (+)3{,}728.41 & \\ (-)\underline{1{,}861.16} & \text{(add algebraically)} \\ (+)1{,}867.25 & \end{array}$$

The rule of sign reversal applies likewise to negative numbers. Thus, if -3 is to be *subtracted* from $+5$, this may be written $+5-(-3)=5+3=8$.

In the algebraic addition of two numbers of opposite sign (numerical subtraction), the smaller number is subtracted from the larger and the result is given the sign of the larger number. Thus, $+7-4=+3$, and $-7+4=-3$, which is the same as $+4-7=-3$.

In navigation, numbers to be numerically subtracted are usually marked (−), and those to be numerically added are marked (+) or the sign is not indicated. However, when a sign is part of a designation, and the reverse process is to be used, the word "reversed" (rev.) is written after the number. Thus, if GMT is known and ZT in the (+)5 zone is to be found (by subtraction), the problem may be written:

$$\begin{array}{lr} \text{GMT} & 1754 \\ \text{ZD} & (+)\underline{5} \ \text{(rev.)} \\ \text{ZT} & 1254 \end{array}$$

The symbol $\sim$ indicates that an absolute difference is required without regard to sign of the *answer*. Thus, $28\sim13=15$, and $13\sim28=15$. In both of these solutions 13 and 28 are positive and 15 is an absolute value without sign. If the signs or names of both numbers are the same, either positive or negative, the smaller is subtracted from the larger, but if they are of opposite sign or name, they are numerically added. Thus, $(+)16\sim(+)21=5$ and $(-)16\sim(-)21=5$, but $(+)16\sim(-)21=37$ and $(-)16\sim(+)21=37$. Similarly, the difference of latitude between 15° N and 20° N, or between 15° S and 20° S, is 5°, but the difference of latitude between 15° N and 20° S, or between 15° S and 20° N, is 35°. If motion from one latitude to another is involved, the difference may be given a sign to indicate the direction of travel, or the location of one place with respect to another. Thus, if B is 50 miles west of A, and C is 125 miles west of A, B and C are 75 miles apart regardless of the direction of travel. However, B is 75 miles *east* of C, and C is 75 miles *west* of B. When direction is indicated, an algebraic difference is given, rather than an absolute difference, and the symbol $\sim$ is not appropriate.

It is sometimes desirable to consider all addition and subtraction problems as addition, with negative signs (−) given before those numbers to be subtracted, so that there can be no question of which process is intended. The words "add" and "subtract" may be used instead of signs. In navigation, "names" (usually north, south, east, and west) are often used, and the relationship involved in a certain problem may need to be understood to determine whether to add or subtract. Thus, $LHA=GHA-\lambda$(west) and $LHA=GHA+\lambda$(east). This is the same as saying $LHA=GHA-\lambda$ if west longitude is considered positive, for in this case, $LHA=GHA-(-\lambda)$ or $LHA=GHA+\lambda$ in east longitude, the same as before.

If numbers are **subtracted arithmetically,** they are subtracted without regard to sign; but if they are **subtracted algebraically,** positive (+) numbers are *subtracted* and negative (−) numbers are *added.*

An answer obtained by subtraction is called a **difference.**

O8. Multiplication may be indicated by the multiplication sign (×), as $154\times28=4{,}312$. For solution, the problem is conveniently arranged thus:

$$\begin{array}{r} 154 \\ (\times)\ 28 \\ \hline 1232 \\ 308 \\ \hline 4312. \end{array}$$

Either number may be given first, but it is generally more convenient to perform the multiplication if the larger number is placed on top, as shown. In this problem, 154 is first multiplied by 8 and then by 2. The second answer is placed under the first, but set one **place** to the left, so that the right-hand digit is directly below the 2. These steps might be reversed, multiplication by 2 being performed first. This procedure is sometimes used in estimating.

When one number is placed below another for multiplication, as shown above, it is usually best to align the right-hand digits without regard for the position of the

decimal point. The number of decimal places in the answer is the sum of the decimal places in the **multiplicand** (the number to be multiplied) and the **multiplier** (the second number):

$$\begin{array}{r} 163.27 \\ (\times)\ 263.9 \\ \hline 146943 \\ 48981 \\ 97962 \\ 32654 \\ \hline 43086.953 \end{array}$$

However, when a number ends in one or more zeros, these may be ignored until the end and then added on to the number:

$$\begin{array}{r} 1924 \\ (\times)\ 1800 \\ \hline 15392 \\ 1924 \\ \hline 3463200. \end{array}$$

This is also true if both multiplicand and multiplier end in zeros:

$$\begin{array}{r} 1924000 \\ (\times)\ 1800 \\ \hline 15392 \\ 1924 \\ \hline 3463200000. \end{array}$$

When negative values are to be multiplied, the sign of the answer is positive if an *even* number of negative signs appear, and negative if there are an *odd* number. Thus, $2\times3=6$, $2\times(-3)=-6$, $-2\times3=-6$, $-2\times(-3)=(+)6$. Also, $2\times3\times8\times(-2)\times5=-480$, $2\times(-3)\times8\times(-2)\times5=480$, $2\times(-3)\times(-8)\times(-2)\times5=-480$, $2\times(-3)\times(-8)\times(-2)\times(-5)=480$, and $(-2)\times(-3)\times(-8)\times(-2)\times(-5)=-480$.

An answer obtained by multiplication is called a **product.** Any number multiplied by 1 is the number itself. Thus, $125\times1=125$. Any number multiplied by 0 is 0. Thus, $125\times0=0$ and $1\times0=0$.

To multiply a number by itself is to **square** the number. This may be indicated by the **exponent** 2 placed to the right of the number and above the line as a **superior.** Thus, 15×15 may be written 15^2. Similarly, $15\times15\times15=15^3$, and $15\times15\times15\times15=15^4$, etc. The exponent (2, 3, 4, etc.) indicates the **power** to which a number is to be **raised,** or how many times the number is to be used in multiplication. The expression 15^2 is usually read "15 squared," 15^3 is read "15 cubed" or "15 to the third power," 15^4 (or higher power) is read "15 to the fourth (or higher) power." The answer obtained by **raising to a power** is called the "square," "cube," etc., or the " . . . power" of the number. Thus, 225 is the "square of 15," 3,375 is the "cube of 15" or the "third power of 15," etc. The zero power of any number except zero (if zero is considered a number) is 1. The zero power of zero is zero. Thus, $15^0=1$ and $0^0=0$.

Parentheses may be used to eliminate doubt as to what part of an expression is to be raised to a power. Thus, -3^2 may mean either $-(3\times3)=-9$ or $-3\times-3=(+)9$. To remove the ambiguity, the expression may be written $-(3)^2$ if the first meaning is intended, and $(-3)^2$ if the second meaning is intended.

O9. Division is the inverse of multiplication. It may be indicated by the division sign ($\div$), as $376 \div 21 = 18$ approximately; or by placing the number to be divided, called the **dividend** (376), over the other number, called the **divisor** (21), as $\frac{376}{21} = 18$ approximately. The expression $\frac{376}{21}$ may be written 376/21 with the same meaning. Such a problem is conveniently arranged for solution as follows:

$$
\begin{array}{r|r}
 & 17 \\ \hline
21 & 376 \\
 & 21 \\ \cline{2-2}
 & 166 \\
 & 147 \\ \cline{2-2}
 & 19.
\end{array}
$$

Since the **remainder** is 19, or more than half of the divisor (21), the answer is 18 to the nearest whole number.

An answer obtained by division is called a **quotient.** Any number divided by 1 is the number itself. Thus, $65 \div 1 = 65$. A number cannot be divided by 0.

If the numbers involved are accurate only to the number of places given, the answer should not be carried to additional places. However, if the numbers are exact, the answer might be carried to as many decimal places as desired. Thus, $374 \div 21 = 17.809523809523809523809523809523 \ldots$ When a series of digits repeat themselves with the same remainder, as 809523 (with remainder 17) in the example given above, an exact answer will not be obtained regardless of the number of places to which the division is carried. The series of dots (. . .) indicates a **repeating decimal.** In a nonrepeating decimal, a plus sign (+) may be given to indicate a remainder, and a minus sign (−) to indicate that the last digit has been rounded to the next higher value. Thus, 18.68761 may be written 18.6876+ or 18.688−. If the last digit given is rounded off, the word "approximately" may be used instead of dots or a plus or minus sign.

If the divisor is a whole number, the decimal point in the quotient is directly above that of the dividend when the work form shown above is used. Thus, in the example given above, if the dividend had been 37.6 instead of 376, the quotient would have been 1.8 approximately. If the divisor is a decimal, both it and the dividend are multiplied by the power of 10 having an exponent equal to the number of decimal places in the divisor, and the division is then carried out as explained above. Thus, if there are two decimal places in the divisor, both divisor and dividend are multiplied by $10^2 = 100$. This is done by moving the decimal to the right until the divisor is a whole number. If necessary, zeros are added to the dividend. Thus, if 3.7 is to be divided by 2.11, both quantities are first multiplied by 10^2, and 370 is divided by 211. This is usually performed as follows:

$$
\begin{array}{r|r}
 & 1.75 \\ \hline
2_{\wedge}11 & 3_{\wedge}70.00 \\
 & 211 \\ \cline{2-2}
 & 1590 \\
 & 1477 \\ \cline{2-2}
 & 1130 \\
 & 1055 \\ \cline{2-2}
 & 75.
\end{array}
$$

If *both* the dividend and divisor are positive, or if *both* are negative, the quotient is positive; but if *either* is negative, the quotient is negative. Thus, $6 \div 3 = 2$, $(-6) \div (-3) = +2$, $(-6) \div 3 = -2$, and $6 \div (-3) = -2$.

The **square root** of a number is that number which, multiplied by itself, equals the given number. Thus, $15 \times 15 = 15^2 = 225$, and $\sqrt{225} = 225^{1/2} = 15$. Either the symbol $\sqrt{\ }$, called the **radical sign,** or the exponent ½ indicates square root. Also, $\sqrt[3]{\ }$, or ⅓ as an exponent, indicates **cube root.** Fourth, fifth, or any root is indicated similarly, using the appropriate number. Nearly any arithmetic book explains the process of extracting roots, but this process is most easily performed by table, logarithms (art. O12), or slide rule (art. O15). If no other means are available, it can be done by trial and error. The process of finding a root of a number is called **extracting a root.**

O10. Logarithms ("logs") provide an easy way to multiply, divide, raise numbers to powers, and extract roots. The logarithm of a number is the power to which a fixed number, called the base, must be raised to produce the value to which the logarithm corresponds. The base of **common logarithms,** (given in tables 32 and 33) is 10. Hence, since $10^{1.8} = 63$ approximately, 1.8 is the logarithm, approximately, of 63 to the base 10. In table 32 logarithms of numbers are given to five decimal **places.** This is sufficient for most purposes of the navigator. For greater precision, a table having additional places should be used. In general, the number of *significant digits* which are correct in an answer obtained by logarithms is the same as the number of *places* in the logarithms used.

A logarithm is composed of two parts. That part to the left of the decimal point is called the **characteristic.** That part to the right of the decimal point is called the **mantissa.** The principal advantage of using 10 as the base is that any given combination of digits has the same mantissa regardless of the position of the decimal point. Hence, only the mantissa is given in the main tabulation of table 32. Thus, the logarithm (mantissa) of 2,374 is given as 37548. This is correct for 2,374,000,000; 2,374; 23.74; 2.374; 0.2374; 0.000002374; or for any other position of the decimal point.

The position of the decimal point determines the characteristic, which is not affected by the actual digits involved. The characteristic of a whole number is one less than the number of digits. The characteristic of a **mixed decimal** (one greater than 1) is one less than the number of digits to the left of the decimal point. Thus, in the example given above, the characteristic of the logarithm of 2,374,000,000 is 9; that of 2,374 is 3; that of 23.74 is 1; and that of 2.374 is 0. The complete logarithms of these numbers are:

$$\begin{aligned}
\log 2{,}374{,}000{,}000 &= 9.37548 \\
\log 2{,}374 &= 3.37548 \\
\log 23.74 &= 1.37548 \\
\log 2.374 &= 0.37548.
\end{aligned}$$

Since the mantissa of the logarithm of any multiple of ten is zero, the main table starts with 1,000. This can be considered 100, 10, 1, etc. Since the mantissa of these logarithms is zero, the logarithms consist of the characteristic only, and are whole numbers. Hence, the logarithm of 1 is 0 (0.00000), that of 10 is 1 (1.00000), that of 100 is 2 (2.00000), that of 1,000 is 3 (3.00000), etc.

The characteristic of the logarithm of a number less than 1 is negative. However, it is usually more conveniently indicated in a positive form, as follows: the characteristic is found by subtracting the number of zeros immediately to the right of the decimal point from 9 (or 19, 29, etc.) and following this by −10 (or −20, −30, etc.). Thus, the

characteristic of the logarithm of 0.2374 is 9−10; that of 0.000002374 is 4−10; and that of 0.000000000002374 is 8−20. The complete logarithms of these numbers are:

$$\begin{aligned}\log 0.2374 &= 9.37548-10\\ \log 0.000002374 &= 4.37548-10\\ \log 0.000000000002374 &= 8.37548-20.\end{aligned}$$

When there is no question of the meaning, the −10 may be omitted. This is usually done when using logarithms of trigonometric functions, as shown in table 33. Thus, if there is no reasonable possibility of confusion, the logarithm of 0.2374 may be written 9.37548.

Occasionally, the logarithm of a number less than 1 is shown by giving the negative characteristic with a minus sign above it (since only the characteristic is negative, the mantissa being positive). Thus, the logarithms of the numbers given above might be shown thus:

$$\begin{aligned}\log 0.2374 &= \bar{1}.37548\\ \log 0.000002374 &= \bar{6}.37548\\ \log 0.000000000002374 &= \overline{12}.37548.\end{aligned}$$

In each case, the negative characteristic is one *more* than the number of zeros immediately to the right of the decimal point.

There is no real logarithm of 0, since there is no *finite* power to which *any* number can be raised to produce 0. As numbers approach 0, their logarithms approach negative infinity.

To find the number corresponding to a given logarithm, called finding the **antilogarithm** ("antilog"), enter the table with the mantissa of the given logarithm and determine the corresponding number, interpolating if necessary. Locate the position of the decimal point by means of the characteristic of the logarithm, in accordance with the rules given above.

O11. Multiplication by logarithms.—To *multiply* one number by another, *add* their logarithms and find the antilogarithm of the sum. Thus, to multiply 1,635.8 by 0.0362 by logarithms:

$$\begin{aligned}\log 1635.8 &= 3.21373\\ \log 0.0362 &= \underline{8.55871-10}\ \text{(add)}\\ \log 59.216 &= 11.77244-10 \text{ or } 1.77244.\end{aligned}$$

Thus, $1{,}635.8 \times 0.0362 = 59.216$. In navigation it is customary to use a slightly modified form, and to omit the −10 where there is no reasonable possibility of confusion, as follows:

$$\begin{array}{ll} 1635.8 & \log 3.21373\\ 0.0362 & \log \underline{8.55871}\\ 59.216 & \log 1.77244. \end{array}$$

To *raise a number to a power*, multiply the logarithm of that number by the power indicated, and find the antilogarithm of the product. Thus, to find 13.156^3 by logarithms, using the navigational form:

$$\begin{array}{lr} 13.156 & \log 1.11913\\ & \times\ \underline{3}\ \text{(multiply)}\\ 2277.2 & \log 3.35739. \end{array}$$

O12. Division by logarithms.—To *divide* one number by another, subtract the logarithm of the divisor from that of the dividend, and find the antilogarithm of the remainder. Thus, to find 0.4637÷28.03 by logarithms, using the navigational form:

$$\begin{array}{rll} 0.4637 & \log & 9.66624 \\ 28.03 & \log\ (-) & \underline{1.44762}\ \text{(subtract)} \\ 0.016543 & \log & 8.21862. \end{array}$$

It is sometimes necessary to modify the first logarithm before the subtraction can be made. This would occur in the example given above, for instance, if the divisor and dividend were reversed, so that the problem became 28.03÷0.4637. In this case 10−10 would be added to the logarithm of the dividend, becoming 11.44762−10:

$$\begin{array}{rll} 28.03 & \log & 11.44762-10 \\ 0.4637 & \log\ (-) & \underline{9.66624-10} \\ 60.448 & \log & 1.78138. \end{array}$$

One experienced in the use of logarithms usually carries this change mentally, without showing it in his work form:

$$\begin{array}{rll} 28.03 & \log & 1.44762 \\ 0.4637 & \log\ (-) & \underline{9.66624} \\ 60.448 & \log & 1.78138. \end{array}$$

Any number can be added to the characteristic as long as that same number is also subtracted. Conversely, any number can be subtracted from the characteristic as long as that same number is also added.

To *extract a root* of a number, divide the logarithm of that number by the root indicated, and find the antilogarithm of the quotient. Thus, to find $\sqrt{7}$ by logarithms:

$$\begin{array}{rl} 7 & \log\ \underline{0.84510}\ (\div 2) \\ 2.6458 & \log\ 0.42255. \end{array}$$

To divide a negative logarithm by the root indicated, first modify the logarithm so that the quotient will have a −10. Thus, to find $\sqrt[3]{0.7}$ by logarithms:

$$\begin{array}{rl} 0.7 & \log\ \underline{29.84510-30}\ (\div 3) \\ 0.88792 & \log\ \ 9.94837-10 \end{array}$$

or, carrying the −30 and −10 mentally,

$$\begin{array}{rl} 0.7 & \log\ \underline{29.84510}\ (\div 3) \\ 0.88792 & \log\ \ 9.94837. \end{array}$$

O13. Cologarithms.—The **cologarithm** ("colog") of a number is the value obtained by subtracting the logarithm of that number from zero, usually in the form 10−10. Thus, the logarithm of 18.615 is 1.26987. The cologarithm is:

$$\begin{array}{r} 10.00000-10 \\ (-)\underline{1.26987\qquad} \\ 8.73013-10. \end{array}$$

Similarly, the logarithm of 0.0018615 is 7.26987−10, and its cologarithm is:

$$\begin{array}{r} 10.00000-10 \\ (-)\underline{7.26987-10} \\ 2.73013. \end{array}$$

The *cologarithm* of a number is the *logarithm* of the reciprocal of that number. Thus, the cologarithm of 2 is the logarithm of ½. Since division by a number is the same as multiplication by its reciprocal, the use of cologarithms permits division problems to be converted to problems of multiplication, eliminating the need for subtraction of logarithms. This is particularly useful when both multiplication and division are involved in the same problem. Thus, to find $\frac{92.732\times 0.0137\times 724.3}{0.516\times 3941.1}$ by logarithms, one might *add* the logarithms of the three numbers in the numerator, and *subtract* the logarithms of the two numbers in the denominator. If cologarithms are used for the numbers in the denominator, all logarithmic values are added. Thus, the solution might be made as follows:

92.732		log 1.96723
0.0137		log 8.13672
724.3		log 2.85992
0.516	log 9.71265	colog 0.28735
3941.1	log 3.59562	colog 6.40438
0.45248		log 9.65560.

O14. Various kinds of logarithms.—As indicated above, **common logarithms** use 10 as the base. These are also called **Briggs' logarithms.** For some purposes, it is convenient to use 2.7182818 approximately (designated e) as the base for logarithms. These are called **natural logarithms** or **Naperian logarithms** ($\log_e$). Common logarithms are shown as $\log_{10}$ when the base might otherwise be in doubt.

Addition and subtraction logarithms are logarithms of the sum and difference of two numbers. They are used when the logarithms of two numbers to be added or subtracted are known, making it unnecessary to find the numbers themselves.

O15. Slide rule.—A **slide rule** is a convenient device for making logarithmic solutions mechanically. There are many types and sizes of slide rule, some designed for specific purposes. The most common form consists of an outer "body" or "frame" with grooves to permit a "slide" to be moved back and forth between the two outer parts, so that any graduation of a scale on the slide can be brought opposite any graduation of a scale on the body. A cursor called an "indicator" or "runner" is provided to assist in aligning the desired graduations. In a **circular slide rule** the "slide" is an inner disk surrounded by a larger one, both pivoted at their common center. The scales of a slide rule are *logarithmic*. That is, they increase proportionally to the logarithms of the numbers indicated, rather than to the numbers themselves. This permits addition and subtraction of logarithms by simply measuring off part of the length of the slide from a graduated point on the body, or vice versa. Two or three complete scales within the length of the rule may be provided for finding squares, cubes, square roots, and cube roots.

Full instructions for use of a slide rule are provided with each rule, and given in some mathematical texts. Properly used, a slide rule can provide quick answers to many of the problems of navigation. However, its precision is usually limited to from two to four significant digits, and should not be used if greater precision is desired. It is frequently used to provide a quick, approximate check on answers obtained by a more laborious method.

Great care should be used in placing the decimal point in an answer obtained by slide rule, as the correct location often is not immediately apparent. Its position is usually determined by making a very rough mental solution. Thus, 2.93×8.3 is *about* $3\times 8=24$. Hence, when the answer by slide rule is determined to be "243," it is known that the correct value is 24.3, not 2.43 or 243.

O16. Mental arithmetic.—Many of the problems of the navigator can be solved mentally. The following are a few examples.

If the speed is a number divisible into 60 a whole number of times, distance problems can be solved by a simple relationship. Thus, at 10 knots a ship steams 1 mile in $\frac{60}{10}=6$ minutes. At 12 knots it requires 5 minutes, at 15 knots 4 minutes, etc. As an example of the use of such a relationship, a vessel steaming at 12 knots travels 5.6 miles in 28 minutes, since $\frac{28}{5}=5\frac{3}{5}=5.6$, or 0.1 mile every half minute.

For relatively short distances, one nautical mile can be considered equal to 6,000 feet. Since one hour has 60 minutes, the speed in hundreds of feet per minute is equal to the speed in knots. Thus, a vessel steaming at 15 knots is moving at the rate of 1,500 feet per minute.

With respect to time, 6 minutes $=0.1$ hour, and 3 minutes $=0.05$ hour. Hence, a ship steaming at 13 knots travels 3.9 miles in 18 minutes (13×0.3), and 5.8 miles in 27 minutes (13×0.45).

In arc units, $6'=0\overset{\circ}{.}1$ and $6''=0\overset{'}{.}1$. This relationship is useful in rounding off values given in arc units. Thus, $17°23'44''=17°23\overset{'}{.}7$ to the nearest $0\overset{'}{.}1$, and $17\overset{\circ}{.}4$ to the nearest $0\overset{\circ}{.}1$. A thorough knowledge of the six multiplication table is valuable. The 15 multiplication table is also useful, since $15°=1^h$. Hence, $16^h=16\times15=240°$. This is particularly helpful in quick determination of zone description. Pencil and paper or a table should not be needed, for instance, to decide that a ship at sea in longitude $157°18\overset{'}{.}4$ W is in the (+)10 zone.

It is also helpful to remember that $1°=4^m$ and $1'=4^s$. In converting the LMT of sunset to ZT, for instance, a quick mental solution can be made without reference to a table. Since this correction is usually desired only to the nearest whole minute, it is necessary only to multiply the longitude difference in degrees (to the nearest quarter degree) by four.

Vectors

O17. Scalars and vector quantities.—A **scalar** is a quantity which has *magnitude* only; a **vector quantity** has both *magnitude* and *direction*. If a vessel is said to have a tank of 5,000 gallons capacity, the number 5,000 is a scalar. As used in this book, *speed* alone is considered a scalar, while *speed* and *direction* are considered to constitute *velocity*, a vector quantity. Thus, if a vessel is said to be steaming at 18 knots, without regard to direction, the number 18 is considered a scalar; but if the vessel is said to be steaming at 18 knots on course 157°, the combination of 18 knots and 157° constitutes a vector quantity. *Distance* and *direction* also constitute a vector quantity.

A *scalar* can be represented fully by a number. A *vector quantity* requires, in addition, an indication of direction. This is conveniently done graphically by means of a straight line, the length of which indicates the *magnitude*, and the direction of which indicates the *direction* of application of the magnitude. Such a line is called a **vector.** Since a straight line has two directions, reciprocals of each other, an arrowhead is placed along or at one end of a vector to indicate the direction represented, unless this is apparent or indicated in some other manner.

O18. Addition and subtraction of vectors.—Two vectors can be *added* by *starting* the second at the *termination* (rather than the origin) of the first. A common navigational use of vectors is the dead reckoning plot of a vessel. Refer to figure O18. If a ship starts at A and steams 18 miles on course 090° and then 12 miles on course 060°, it arrives by dead reckoning at C. The line AB is the vector for the first run, and

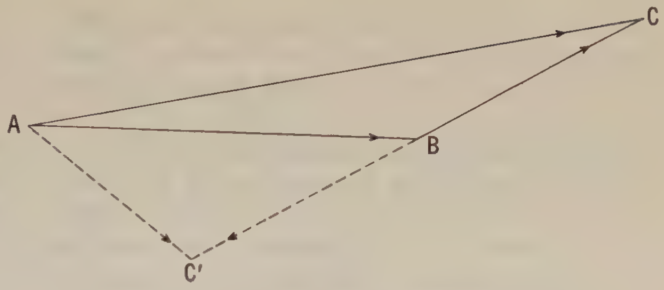


FIGURE O18. Addition and subtraction of vectors.

BC is the vector for the second. Point C is the position found by *adding* vectors AB and BC. The vector AC, in this case the *course and distance made good*, is the **resultant.** Its value, both in direction and amount, can be determined by measurement. Lines AB, BC, and AC are all **distance vectors. Velocity vectors** are used when determining the effect of, or allowing for, current (art. 807) or interconverting true and apparent wind (art. 3709).

The **reciprocal** of a vector has the same magnitude but opposite direction of the vector. To *subtract* a vector, *add* its reciprocal. This is indicated by the broken lines in figure O18, in which the vector BC' is drawn in the opposite direction to BC. In this case the resultant is AC'. Subtraction of vectors is involved in some current and wind problems.

Algebra

O19. Definitions.—**Algebra** is that branch of mathematics dealing with computation by letters and symbols. It permits the mathematical statement of certain relationships between variables. When numbers are substituted for the letters, algebra becomes arithmetic. Thus if $a=2b$, any value may be assigned to b, and a can be found by multiplying the assigned value by 2. Any statement of equality (as $a=2b$) is an **equation.** Any combination of numbers, letters, and symbols (as $2b$) is a **mathematical expression.**

O20. Symbols.—As in arithmetic, plus (+) and minus (−) signs are used, and with the same meaning. Multiplication (×) and division (÷) signs are seldom used. In algebra, $a \times b$ is usually written ab, or sometimes $a \cdot b$. For division $a \div b$ is usually written $\frac{a}{b}$ or a/b. The symbol $>$ means "greater than" and $<$ means "less than." Thus, $a>b$ means "a is greater than b," and $a \geqq b$ or $a \geq b$ means "a is equal to or greater than b."

The order of performing the operations indicated in an equation should be observed carefully. Consider the equation $a=b+cd-e/f$. If the equation is to be solved for a, the value cd should be determined by multiplication and e/f by division *before* the addition and subtraction, as each of these is to be considered a single quantity in making the addition and subtraction. Thus, if $cd=g$ and $e/f=h$, the formula can be written $a=b+g-h$.

If an equation including both multiplication and division between plus or minus signs is not carefully written, some doubt may arise as to which process to perform first. Thus, $a \div b \times c$ or $a/b \times c$ may be interpreted to mean either that a/b is to be multiplied by c or that a is to be divided by $b \times c$. Such an equation is better written ac/b if the first meaning is intended, or a/bc if the second meaning is intended. **Parentheses,** ( ), may be used for the same purpose or to indicate any group of quantities that is to be considered a single quantity. Thus, $a(b+c)$ is an indication that the sum of b and c is to be multiplied by a. Similarly, $a+(b-c)^2$ indicates that c is first to be subtracted from b, and then the result is to be squared and the value thus obtained added to a. When an expression within parentheses is part of a larger expression

which should also be in parentheses, **brackets,** [ ], are used in place of the outer parentheses. If yet another set is needed, **braces,** { }, are used.

A quantity written $\sqrt{3}\, ab$ is better written $ab\sqrt{3}$ to remove any suggestion that the square root of $3ab$ is to be found.

O21. Addition and subtraction.—A plus sign before an expression in parentheses means that each term retains its sign as given. Thus, $a+(b+c-d)$ is the same as $a+b+c-d$. A minus sign preceding the parentheses means that each sign within the parentheses is to be reversed. For example, $a-(b+c-d)=a-b-c+d$.

In any equation involving addition and subtraction, similar terms can be combined. Thus, $a+b+c+b-2c-d=a+2b-c-d$. Also, $a+3ab+a^2-b-ab=a+2ab+a^2-b$. That is, to be combined, the terms must be truly alike, for a cannot be combined with ab, or with a^2.

Equal quantities can be added to or subtracted from both members of an equation without disturbing the equality. Thus, if $a=b$, $a+2=b+2$, or $a+x=b+x$. If $x=y$, then $a+x=b+y$.

O22. Multiplication and division.—When an expression in parentheses is to be multiplied by a quantity outside the parentheses, each quantity separated by a plus or minus sign within the parentheses should be multiplied separately. Thus, $a(b+cd-e/f)$ may be written $ab+acd-ae/f$. Any quantity appearing in *every* term of one member of an equation can be separated out by **factoring,** or dividing each term by the common quantity. Thus, if $a=bc+\frac{bd}{e}-b^2+b$, the equation may be written $a=b\left(c+\frac{d}{e}-b+1\right)$.

Note that $\frac{b}{b}=1$ and $\frac{b^2}{b}=b$. This is the inverse of multiplication: $a\times 1=a$, but $a\times a=a^2$. Also, $a^2\times a^3=a^5$; and $\frac{a^7}{a^2}=a^5$. Thus, in multiplying a power of a number by a power of the same number, the powers are added, or, stated mathematically, $a^m\times a^n=a^{m+n}$. In division, $\frac{a^m}{a^n}=a^{m-n}$, or the exponents are subtracted. If n is greater than m, a *negative* exponent results. A value with a negative exponent is equal to the reciprocal of the same value with a positive exponent. Thus, $a^{-n}=\frac{1}{a^n}$ and $\frac{a^2\, b^{-3}}{c}=\frac{a^2}{b^3c}$.

In raising to a power a number with an exponent, the two exponents are multiplied. Thus, $(a^2)^3=a^{2\times 3}=a^6$, or $(a^n)^m=a^{nm}$. The inverse is true in extracting a root. Thus, $\sqrt[3]{a^2}=a^{\frac{2}{3}}=a^{0.667}$, or $\sqrt[m]{a^n}=a^{\frac{n}{m}}$.

Both members of an equation can be multiplied or divided by equal quantities without disturbing the equality, excluding division by zero or some expression equal to zero. Thus, if $a=b+c$, $2a=2(b+c)$, or if $x=y$, $ax=y(b+c)$ and $\frac{a}{x}=\frac{b+c}{y}$. Sometimes there is more than one answer to an equation. Division by one of the unknowns may eliminate one of the answers.

Both members of an equation can be raised to the same power, and like roots of both members can be taken, without disturbing the equality. Thus, if $a=b+c$, $a^2=(b+c)^2$, or if $x=y$, $a^x=(b+c)^y$. This is *not* the same as $a^x=b^y+c^y$. Similarly, if $a=b+c$, $\sqrt{a}=\sqrt{b+c}$, or if $x=y$, $\sqrt[x]{a}=\sqrt[y]{b+c}$. Again, $\sqrt[y]{b+c}$ is *not* equal to $\sqrt[y]{b}+\sqrt[y]{c}$, as a numerical example will indicate: $\sqrt{100}=\sqrt{64+36}$, but $\sqrt{100}$ does not equal $\sqrt{64}+\sqrt{36}$.

If two quantities to be multiplied or divided are *both* positive or *both* negative, the result is positive. Thus, $(+a)\times(+b)=ab$ and $\frac{-a}{-b}=+\frac{a}{b}$. But if the signs are opposite,

the answer is negative. Thus, $(+a)\times(-b)=-ab$, and $\frac{-a}{+b}=-\frac{a}{b}$; also, $(-a)\times(+b)=-ab$, and $\frac{+a}{-b}=-\frac{a}{b}$.

In expressions containing both parentheses and brackets, or both of these and braces, the innermost symbols are removed first. Thus, $-\left\{6z-\frac{[x(x+4)-5y]}{y}\right\}=-\left\{6z-\frac{[x^2+4x-5y]}{y}\right\}=-\left\{6z-\frac{x^2}{y}-\frac{4x}{y}+5\right\}=-6z+\frac{x^2}{y}+\frac{4x}{y}-5$.

O23. Fractions.—To add or subtract two or more fractions, convert each to an expression having the same denominator, and then add the numerators. Thus, $\frac{a}{b}+\frac{c}{d}+\frac{e}{f}=\frac{adf}{bdf}+\frac{cbf}{bdf}+\frac{ebd}{bdf}=\frac{adf+cbf+ebd}{bdf}$. That is, both numerator and denominator of each fraction are multiplied by the denominator of the other remaining fractions.

To multiply two or more fractions, multiply the numerators by each other, and also multiply the denominators by each other. Thus, $\frac{a}{b}\times\frac{c}{d}\times\frac{e}{f}=\frac{ace}{bdf}$.

To divide two fractions, invert the divisor and multiply. Thus, $\frac{a}{b}\div\frac{c}{d}=\frac{a}{b}\times\frac{d}{c}=\frac{ad}{bc}$.

If the same factor appears in all terms of a fraction, it can be factored out without changing the value of the fraction. Thus, $\frac{ab+ac+ad}{ae-af}=\frac{b+c+d}{e-f}$. This is the same as factoring a from the numerator and denominator separately. That is, $\frac{ab+ac+ad}{ae-af}=\frac{a(b+c+d)}{a(e-f)}$, but since $\frac{a}{a}=1$, this part can be removed, and the fraction appears as above.

O24. Transposition.—It is sometimes desirable to move terms of an expression from one side of the equals sign (=) to the other. This is called **transposition,** and to move one term is to **transpose** it. If the term to be moved is preceded by a plus or a minus sign, this sign is reversed when the term is transposed. Thus, if $a=b+c$, then $a-b=c$, $a-c=b$, $-b=c-a$, $-b-c=-a$, etc. Note that the signs of *all* terms can be reversed without destroying the equality, for if $a=b$, $b=a$. Thus, if *all* terms to the left of the equals sign are exchanged for *all* those to the right, no change in sign need take place, yet if each is moved individually, the signs reverse. For instance, if $a=b+c$, $-b-c=-a$. If each term is multiplied by -1, this becomes $b+c=a$.

A term which is to be multiplied or divided by *all* other terms on its side of the equation can be transposed if it is also moved from the numerator to the denominator, or vice versa. Thus, if $a=\frac{b}{c}$, then $ac=b$, $c=\frac{b}{a}$, $\frac{1}{b}=\frac{1}{ac}$, $\frac{c}{b}=\frac{1}{a}$, etc. $\left(\text{Note that } a=\frac{a}{1}.\right)$ The same result could be obtained by multiplying both sides of an equation by the same quantity. For instance, if both sides of $a=\frac{b}{c}$ are multiplied by c, the equation becomes $ac=\frac{bc}{c}$ and since any number (except zero) divided by itself is unity, $\frac{c}{c}=1$, and the equation becomes $ac=b$, as given above. Note, also, that *both* sides of an equation can be *inverted* without destroying the relationship, for if $a=b$, $\frac{a}{1}=\frac{b}{1}$, and $\frac{1}{b}=\frac{1}{a}$ or $\frac{1}{a}=\frac{1}{b}$. This is accomplished by transposing *all* terms of an equation.

Note that in the case of transposition by changing the plus or minus sign, an entire expression must be changed, and not a part of it. Thus, if $a=bc+d$, $a-bc=d$, but it

is not true that $a+b=c+d$. Similarly, a term to be transposed by reversing its multiplication-division relationship must bear that relationship to *all* other terms on its side of the equation. That is, if $a=bc+d$, it is *not* true that $\frac{a}{b}=c+d$, or that $\frac{a}{bc}=d$, but $\frac{a}{bc+d}=1$. If $a=b(cd+e)$, then $\frac{a}{b}=cd+e$.

O25. Ratio and proportion.—If the relationship of a to b is the same as that of c to d, this fact can be written $a : b :: c : d$, or $\frac{a}{b}=\frac{c}{d}$. Either side of this equation, $\frac{a}{b}$ or $\frac{c}{d}$ is called a **ratio** and the whole equation is called a **proportion.** When a ratio is given a numerical value, it is often expressed as a decimal or as a percentage. Thus, if $\frac{a}{b}=\frac{1}{4}$ (that is, $a=1$, $b=4$), the ratio might be expressed as 0.25 or as 25 percent.

Since a ratio is a fraction, it can be handled as any other fraction.

Geometry

O26. Definitions.—**Geometry** is that branch of mathematics dealing with the properties, relations, and measurement of lines, surfaces, solids, and angles. **Plane geometry** deals with plane figures, and **solid geometry** deals with three-dimensional figures.

A **point,** considered mathematically, is a place having position but no extent. It has no length, breadth, or thickness. A point in motion produces a **line,** which has length, but neither breadth nor thickness. A **straight** or **right line** is the shortest distance between two points in space. A line in motion in any direction except along itself produces a **surface,** which has length and breadth, but not thickness. A **plane surface** or **plane** is a surface without curvature. A straight line connecting any two of its points lies wholly within the plane. A plane surface in motion in any direction except within its plane produces a **solid,** which has length, breadth, and thickness. **Parallel** lines or surfaces are those which are everywhere equidistant. **Perpendicular** lines or surfaces are those which meet at right angles. A perpendicular may be called a **normal,** particularly when it is perpendicular to the tangent to a curved line or surface at the point of tangency. All points equidistant from the ends of a straight line are on the perpendicular bisector of that line. The distance from a point to a line is the length of the perpendicular between them, unless some other distance is indicated.

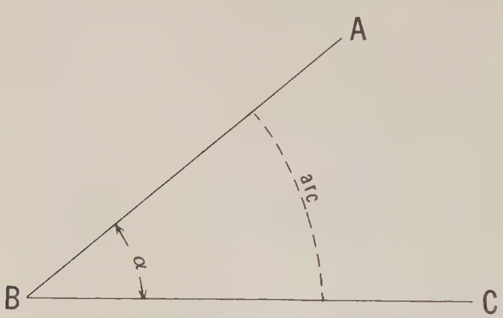

FIGURE O27a. An angle.

O27. Angles.—An **angle** is the inclination to each other of two straight lines which meet at a point. It is measured by the arc of a circle intercepted between the two lines forming the angle, the center of the circle being at the point of intersection. Referring to figure O27a, the angle formed by lines AB and BC, measured by the arc shown, may be designated "angle B," "angle ABC," or "angle CBA"; or by Greek letter (app. B), as "angle α." The first method should not be used if there is more than one angle at the point, as at G in figure O27b. When three letters are used, the middle one should always be that at the **vertex** of the angle, as G in figure O27b.

An **acute angle** is one less than a right angle (90°). In figure O27b, angles AGB, BGC, CGD, DGE, and EGF are all acute angles.

A **right angle** is one whose sides are perpendicular (90°). In figure O27b, angles *AGC*, *BGD*, *CGE*, and *DGF* are right angles.

An **obtuse angle** is one greater than a right angle (90°) but less than a straight angle (180°). In figure O27b, angles *AGD*, *BGE*, and *CGF* are obtuse angles. Angle *AGF* is also obtuse if measured counterclockwise from *AG* to *FG*.

A **straight angle** is one whose sides form a continuous straight line (180°). In figure O27b, angles *AGE* and *BGF* are straight angles.

A **reflex angle** is one greater than a straight angle (180°) but less than a circle (360°). In figure O27b, angle *AGF* is reflex if measured clockwise from *AG* to *FG*. Actually, any two lines meeting at a point form two angles, one less than a straight angle of 180° (unless exactly a straight angle) and the other greater than a straight angle (180°).

An **oblique angle** is any angle not a multiple of 90°.

Two angles whose sum is a right angle (90°) are **complementary angles,** and either is the **complement** of the other. In figure O27b, angles *AGB* and *BGC*, *BGC* and *CGD*, *CGD* and *DGE*, and *DGE* and *EGF* are complementary. The angles need not be adjacent. Angles *AGB* and *DGE*, and angles *BGC* and *EGF* are complementary.

Two angles whose sum is a straight angle (180°) are **supplementary angles,** and either is the **supplement** of the other. In figure O27b, angles *AGB* and *BGE*, *AGC* and *CGE*, *AGD* and *DGE*, *BGC* and *CGF*, *BGD* and *DGF*, *BGE* and *EGF*, and *AGC* and *DGF* are supplementary.

Two angles whose sum is a circle (360°) are **explementary angles,** and either is the **explement** of the other. The two angles formed when any two lines terminate at a common point are explementary.

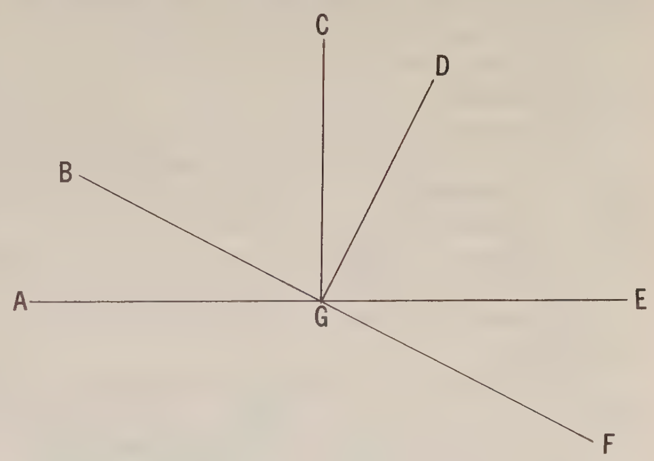

FIGURE O27b. Acute, right, and obtuse angles.

Since angles *AGB* and *CGD* (fig. O27b) are each complementary to angle *BGC*, angles *AGB* and *CGD* are equal. Similarly, it can be shown that angle *EGF* is also equal to angle *CGD* (and therefore also equal to angle *AGB*) and also that angles *BGC* and *DGE* are equal to each other. Since *AGC* and *CGE* are both right angles with a common side, *CG* is perpendicular to *AE*. Similarly, *DG* is perpendicular to *BF*. If the sides of one angle are perpendicular to those of another, the two angles are either equal or supplementary. Also, if the sides of one angle are parallel to those of another, the two angles are either equal or supplementary.

When two straight lines intersect, forming four angles, the two opposite angles, called **vertical angles,** are equal. Thus, in figure O27b, lines *AE* and *BF* intersect at *G*. Angles *AGB* and *EGF* form a pair of equal acute vertical angles, and *BGE* and *AGF* form a pair of equal obtuse vertical angles. Angles which have the same vertex and lie on opposite sides of a common side are **adjacent angles.** Adjacent angles formed by intersecting lines are supplementary, since each pair of adjacent angles forms a straight angle (fig. O27b).

A **transversal** is a line that intersects two or more other lines. If two or more parallel lines are cut by a transversal, groups of adjacent and vertical angles are formed,

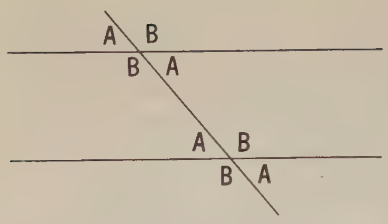

FIGURE O27c. Angles formed by a transversal.

as shown in figure O27c. In this situation, all acute angles (A) are equal, all obtuse angles (B) are equal, and each acute angle is supplementary to each obtuse angle.

A **dihedral angle** is the angle between two intersecting planes.

O28. Triangles.—A **plane triangle** is a closed figure formed by three straight lines, called **sides,** which meet at three points called **vertices** (singular **vertex**). The vertices are usually labeled with capital letters, and the sides with lowercase letters, as shown in figure O28a.

An **equilateral triangle** is one with its three sides equal. An **equiangular triangle** is one with its three angles equal. When either of these conditions is present, the other always is, so that a triangle which is equilateral is also equiangular, and vice versa.

An **isosceles triangle** is one with two equal sides, called **legs.** The angles opposite the legs are equal. A line which bisects (divides into two equal parts) the *unequal* angle of an isosceles triangle is the perpendicular bisector of the opposite side, and divides the triangle into two equal right triangles.

A **scalene triangle** is one with no two sides equal. In such a triangle, no two angles are equal.

An **acute triangle** is one with three acute angles.

A **right triangle** is one with a right angle. The side opposite the right angle is called the **hypotenuse.** The other two sides may be called **legs.** A plane triangle can have only one right angle.

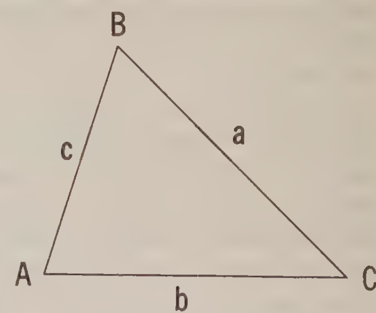

FIGURE O28a. A triangle.

An **obtuse triangle** is one with an obtuse angle. A plane triangle can have only one obtuse angle.

An **oblique triangle** is one which does not contain a right angle.

The **altitude** of a triangle is a perpendicular line from any vertex to the opposite side, extended if necessary, or the length of this perpendicular line.

A **median** of a triangle is a line from any vertex to the center of the opposite side. The three medians of a triangle meet at a point called the **centroid** of the triangle. This point divides each median into two parts, that part between the centroid and the vertex being twice as long as the other part.

Lines bisecting the three angles of a triangle meet at a point which is equidistant from the three sides, and is the center of the **inscribed circle,** as shown in figure O28b. This point is of particular interest to navigators because it is the point taken as the fix when three lines of position of equal weight and having only random errors do not meet at a common point.

The perpendicular bisectors of the three sides of a triangle meet at a point which is equidistant from the three vertices, and is the center of the **circumscribed circle,** the circle through the three vertices and therefore the smallest circle which can be drawn enclosing the triangle. The center of a circumscribed circle is within an acute triangle, on the hypotenuse of a right triangle, and outside an obtuse triangle.

A line connecting the mid points of two sides of a triangle is parallel to the third side and half as long. Also, a line parallel to one side of a triangle and intersecting the other two sides divides these sides proportionally. This principle can be used to divide a line into any number of equal or proportional parts. Refer to figure O28c. Suppose

it is desired to divide line AB into four equal parts. From A draw any line AC. Along C measure four equal parts of any convenient lengths (AD, DE, EF, and FG). Draw GB, and through F, E, and D draw lines parallel to GB and intersecting AB. Then AD', $D'E'$, $E'F'$, and $F'B$ are equal and AB is divided into four equal parts.

The sum of the angles of a plane triangle is 180°. Therefore, the sum of the acute angles of a right triangle is 90°, and the angles are complementary. If one side of a triangle is extended, the **exterior angle** thus formed is supplementary to the adjacent **interior angle** and, therefore, equal to the sum of the two nonadjacent angles. If two angles of one triangle are equal to two angles of another triangle, the third angles are also equal, and the triangles are **similar.** If the area of one triangle is equal to the area of another, the triangles are **equal.** Triangles having equal bases and altitudes have equal areas. Two figures are **congruent** if one can be placed over the other to make an exact fit. Congruent figures are both similar and equal. If any side of one triangle is equal to any side of a similar triangle, the triangles are congruent. For example, if two right triangles have equal sides, they are congruent; if two right triangles have two corresponding sides equal, they are congruent. Triangles are congruent only if the sides and angles are equal.

The sum of two sides of a plane triangle is always greater than the third side; their difference is always less than the third side.

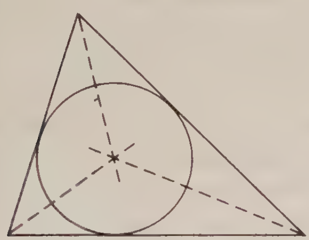

FIGURE O28b. A circle inscribed in a triangle.

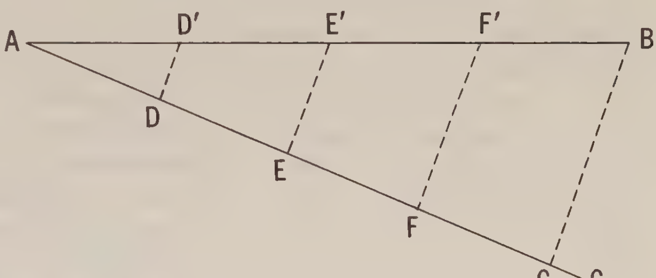

FIGURE O28c. Dividing a line into equal parts.

If A=area, b=one of the legs of a right triangle or the base of any plane triangle, h=altitude, c=the hypotenuse of a right triangle, a=the other leg of a right triangle, and S=the sum of the interior angles:

Area of plane triangle: $A=\frac{bh}{2}$

Length of hypotenuse of plane right triangle: $c=\sqrt{a^2+b^2}$

Sum of interior angles of plane triangle: $S=180°$.

O29. Polygons.—A **polygon** is a closed plane figure made up of three or more straight lines called **sides.** A polygon with three sides is a **triangle,** one with four sides is a **quadrilateral,** one with five sides is a **pentagon,** one with six sides is a **hexagon,** and one with eight sides is an **octagon.** An **equilateral polygon** has equal sides. An **equiangular polygon** has equal interior angles. A **regular polygon** is both equilateral and equiangular. As the number of sides of a regular polygon increases, the figure approaches a circle.

A **trapezoid** is a quadrilateral with one pair of opposite sides parallel and the other pair not parallel. A **parallelogram** is a quadrilateral with both pairs of opposite sides parallel. Any side of a parallelogram, or either of the parallel sides of a trapezoid, is the **base** of the figure. The perpendicular distance from the base to the opposite

side is the altitude. A **rectangle** is a parallelogram with four right angles. (If any one is a right angle, the other three must be, also.) A **square** is a rectangle with equal sides. A **rhomboid** is a parallelogram with oblique angles. A **rhombus** is a rhomboid with equal sides.

The sum of the exterior angles of a convex polygon (one having no interior reflex angles), made by extending each side in one direction only (consistently), is 360°.

A **diagonal** of a polygon is a straight line connecting any two vertices which are not adjacent. The diagonals of a parallelogram bisect each other.

The **perimeter** of a polygon is the sum of the lengths of its sides.

If A=area, s=the side of a square, a=that side of a rectangle adjacent to the base or that side of a trapezoid parallel to the base, b=the base of a quadrilateral, h=the altitude of a parallelogram or trapezoid, S=the sum of the angles of a polygon, and n=the number of sides of a polygon:

Area of square: $A=s^2$
Area of rectangle: $A=ab$
Area of parallelogram: $A=bh$
Area of trapezoid: $A=\frac{(a+b)h}{2}$
Sum of angles in convex polygon: $S=(n-2)180°$.

O30. Circles.—A **circle** is a plane, closed curve, all points of which are equidistant from a point within, called the **center** (C, fig. O30); or the figure formed by such a curve. The line forming the circle is called the **circumference.** The length of this line is the **perimeter,** although the term "circumference" is often used with this meaning. An **arc** is part of a circumference. A **major arc** is more than a semicircle (180°), a **minor arc** is less than a semicircle (180°). A **semicircle** is half a circle (180°), a **quadrant** is a quarter of a circle (90°), a **quintant** is a fifth of a circle (72°), a **sextant** is a sixth of a circle (60°), an **octant** is an eighth of a circle (45°). Some of these names have been applied to instruments used by navigators for measuring altitudes of celestial bodies because of the part of a circle originally used for the length of the arc of the instrument.

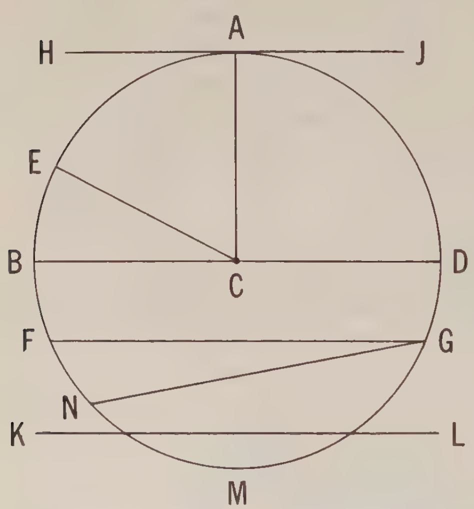

FIGURE O30. Elements of a circle.

Concentric circles have a common center.

A **radius** (plural **radii**) or **semidiameter** is a straight line connecting the center of a circle with any point on its circumference. In figure O30, CA, CB, CD, and CE are radii.

A **diameter** of a circle is a straight line passing through its center and terminating at opposite sides of the circumference, or two radii in opposite directions (BCD, fig. O30). It divides a circle into two equal parts. The ratio of the length of the circumference of any circle to the length of its diameter is 3.14159+, or π (the Greek letter *pi*), a relationship that has many useful applications.

A **sector** is that part of a circle bounded by two radii and an arc. In figure O30, BCE, ECA, ACD, BCA, and ECD are sectors. The angle formed by two radii is called a **central angle.** Any pair of radii divides a circle into sectors, one less than a semicircle (180°) and the other greater than a semicircle (unless the two radii form a diameter).

A **chord** is a straight line connecting any two points on the circumference of a circle (*FG*, *GN* in fig. O30). Chords equidistant from the center of a circle are equal in length.

A **segment** is that part of a circle bounded by a chord and the intercepted arc (*FGMF*, *NGMN* in fig. O30). A chord divides a circle into two segments, one less than a semicircle (180°), and the other greater than a semicircle (unless the chord is a diameter). A diameter perpendicular to a chord bisects it, its arc, and its segments. Either pair of vertical angles formed by intersecting chords has a combined number of degrees equal to the sum of the number of degrees in the two arcs intercepted by the two angles.

An **inscribed angle** is one whose vertex is on the circumference of a circle and whose sides are chords (*FGN* in fig. O30). It has half as many degrees as the arc it intercepts. Hence, an angle inscribed in a semicircle is a right angle if its sides terminate at the ends of the diameter forming the semicircle.

A **secant** of a circle is a line intersecting the circle, or a chord extended beyond the circumference (*KL* in fig. O30).

A **tangent** to a circle is a straight line, in the plane of the circle, which has only one point in common with the circumference (*HJ* in fig. O30). A tangent is perpendicular to the radius at the **point of tangency** (*A* in fig. O30). The two tangents from a point to opposite sides of a circle are equal in length, and a line from the point to the center of the circle bisects the angle formed by the two tangents. An angle formed outside a circle by the intersection of two tangents, a tangent and a secant, or two secants has *half* as many degrees as the *difference* between the two intercepted arcs. An angle formed by a tangent and a chord, with the apex at the point of tangency, has half as many degrees as the arc it intercepts. A **common tangent** is one tangent to more than one circle. Two circles are tangent to each other if they touch at one point only. If of different sizes, the smaller circle may be either inside or outside the larger one.

Parallel lines intersecting a circle intercept equal arcs.

If A=area; r=radius; d=diameter; C=circumference; s=linear length of an arc; α=angular length of an arc, or the angle it subtends at the center of a circle, in degrees; β=angular length of an arc, or the angle it subtends at the center of a circle, in radians; rad=radians (art. O38), and sin=sine (art. O39):

Area of circle: $A=\pi r^2=\dfrac{\pi d^2}{4}$

Circumference of circle: $C=2\pi r=\pi d=2\pi \text{ rad}$

Area of sector: $A=\dfrac{\pi r^2\alpha}{360}=\dfrac{r^2\beta}{2}=\dfrac{rs}{2}$

Area of segment: $A=\dfrac{r^2(\beta-\sin\alpha)}{2}$

O31. Polyhedrons.—A **polyhedron** is a solid having plane sides or **faces.**

A **cube** is a polyhedron having six square sides.

A **prism** is a solid having parallel, similar, equal, plane geometric figures as bases, and parallelograms as sides. By extension, the term is also applied to a similar solid having nonparallel bases, and trapezoids or a combination of trapezoids and parallelograms as sides. The **axis** of a prism is the straight line connecting the centers of its bases. A **right prism** is one having bases perpendicular to the axis. The sides of a right prism are rectangles. A **regular prism** is a right prism having regular polygons as bases. The **altitude** of a prism is the perpendicular distance between the planes of its bases. In the case of a right prism, it is measured along the axis.

A **pyramid** is a polyhedron having a polygon as one end, the **base;** and a point, the **apex,** as the other; the two ends being connected by a number of triangular sides or **faces.** The **axis** of a pyramid is the straight line connecting the apex and the center of the base. A **right pyramid** is one having its base perpendicular to its axis. A **regular pyramid** is a right pyramid having a regular polygon as its base. The **altitude** of a pyramid is the perpendicular distance from its apex to the plane of its base. A **truncated pyramid** is that portion of a pyramid between its base and a plane intersecting all of the faces of the pyramid.

If A=area, s=edge of a cube or slant height of a regular pyramid (from the center of one side of its base to the apex), V=volume, a=side of a polygon, h=altitude, P=perimeter of base, n=number of sides of polygon, B=area of base, and r=perpendicular distance from the center of a side of a polygon to the center of the polygon:

Cube:

Area of each face: $A=s^2$
Total area of all faces: $A=6s^2$
Volume: $V=s^3$

Regular prism:

Area of each face: $A=ah$
Total area of all faces: $A=Ph=nah$
Area of each base: $B=\frac{nar}{2}$
Total area of both bases: $A=nar$
Volume: $V=Bh=\frac{narh}{2}$

Regular pyramid:

Area of each face: $A=\frac{as}{2}$

Total area of all faces: $A=\frac{nas}{2}$

Area of base: $B=\frac{nar}{2}$

Volume: $V=\frac{Bh}{3}=\frac{narh}{6}$.

O32. Cylinders.—A **cylinder** is a solid having two parallel plane **bases** bounded by closed congruent curves, and a surface formed by an infinite number of parallel lines, called **elements,** connecting similar points on the two curves. A cylinder is similar to a prism, but with a curved lateral surface, instead of a number of flat sides connecting the bases. The **axis** of a cylinder is the straight line connecting the centers of the bases. A **right cylinder** is one having bases perpendicular to the axis. A **circular cylinder** is one having circular bases. The **altitude** of a cylinder is the perpendicular distance between the planes of its bases. The **perimeter** of a base is the length of the curve bounding it.

If A=area, P=perimeter of base, h=altitude, r=radius of a circular base, B=area of base, and V=volume, then for a right circular cylinder:

Lateral area: $A=Ph=2\pi rh$
Area of each base: $B=\pi r^2$
Total area, both bases: $A=2\pi r^2$
Volume: $V=Bh=\pi r^2h$.

O33. Cones.—A **cone** is a solid having a plane **base** bounded by a closed curve, and a surface formed by lines, called **elements,** from every point on the curve to a common point called the **apex.** A cone is similar to a pyramid, but with a curved surface connecting the base and apex, instead of a number of flat sides. The **axis** of a cone is the straight line connecting the apex and the center of the base. A **right cone** is one having its base perpendicular to its axis. A **circular cone** is one having a circular base. The **altitude** of a cone is the perpendicular distance from its apex to the plane of its base. A **frustum** of a cone is that portion of the cone between its base and any parallel plane intersecting all elements of the cone. A **truncated cone** is that portion of a cone between its base and any nonparallel plane which intersects all elements of the cone but does not intersect the base.

If A=area, r=radius of base, s=slant height or length of element, B=area of base, h=altitude, and V=volume, then for a right circular cone:

Lateral area: $A=\pi rs$
Area of base: $B=\pi r^2$
Slant height: $s=\sqrt{r^2+h^2}$
Volume: $V=\frac{Bh}{3}=\frac{\pi r^2 h}{3}$.

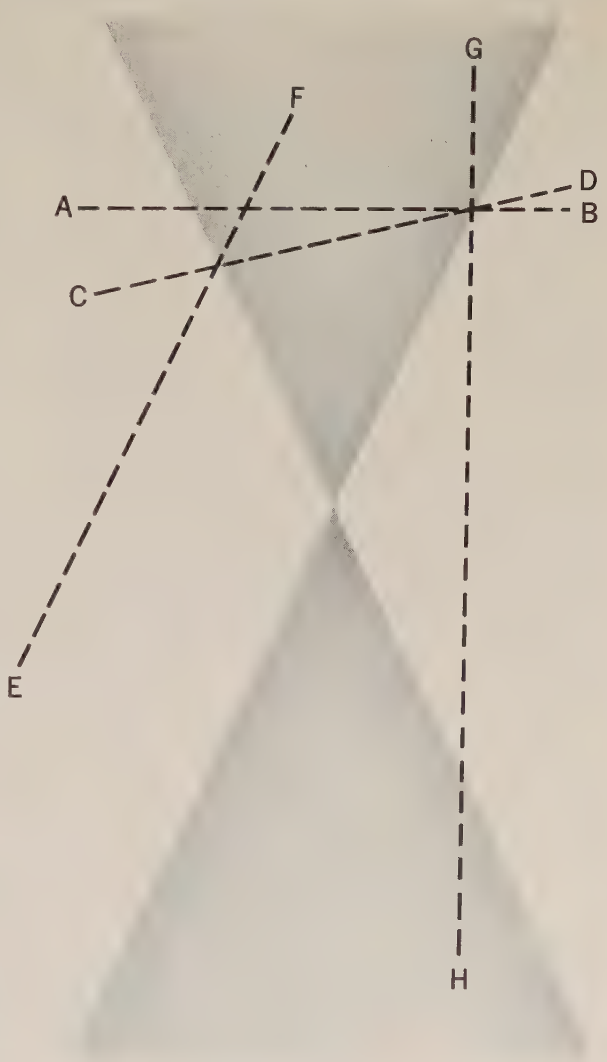

FIGURE O34a. Conic sections.

O34. Conic sections.—If a right circular cone of indefinite extent is intersected by a plane perpendicular to the axis of the cone (AB, fig. O34a), the line of intersection of the plane and the surface of the cone is a **circle,** discussed in article O30.

If the intersecting plane of figure O34a is tilted to some position such as CD, the intersection is an **ellipse** or flattened circle, figure O34b. The longest diameter of an ellipse is called its **major axis,** and half of this is its **semimajor axis,** $\boldsymbol{a}$. The shortest diameter of an ellipse is called its **minor axis,** and half of this is its **semiminor axis,** $\boldsymbol{b}$. Two points, F and F', called **foci** (singular **focus**) or **focal points,** on the major axis are so located that the sum of their distances from any point P on the curve is equal to the length of the major axis. That is, $PF+PF'=2a$ (fig. O34b). The **eccentricity** (e) of an ellipse is equal to $\frac{c}{a}$, where c is the distance from the center to one of the foci ($c=CF=CF'$). It is always greater than 0 but less than 1.

If the intersecting plane of figure O34a is parallel to one element of the cone, as at EF, the intersection is a **parabola,** figure O34c. Any point P on a parabola is equi-

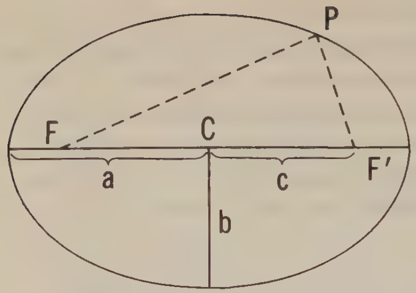

FIGURE O34b. An ellipse.

distant from a fixed point F, called the **focus** or **focal point,** and a fixed straight line, AB, called the **directrix.** Thus, for any point P, $PF=PE$. The point midway between the focus F and the directrix AB is called the **vertex,** V. The straight line through F and V is called the **axis,** CD. This line is perpendicular to the directrix AB. The **eccentricity** (*e*) of a parabola is 1.

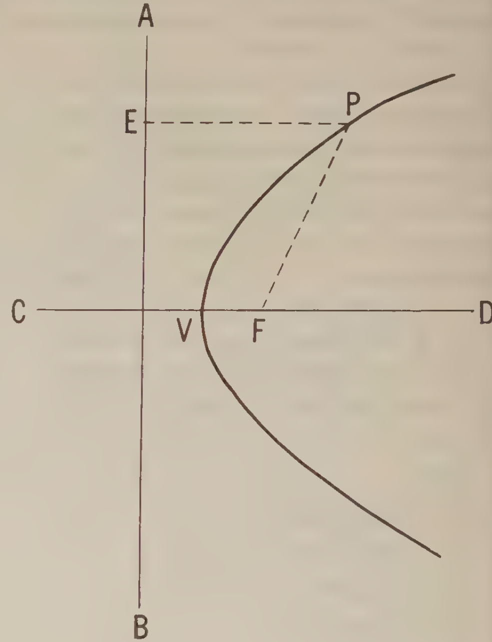

FIGURE O34c. A parabola.

If the elements of the cone of figure O34a are extended to form a second cone having the same axis and apex but extending in the opposite direction, and the intersecting plane is tilted beyond the position forming a parabola, so that it intersects both curves, as at GH, the intersections of the plane with the cones is a **hyperbola,** figure O34d. There are two intersections or branches of a hyperbola, as shown. At any point P on either branch, the *difference* in the distance from two fixed points called **foci** or **focal points,** F and F', is constant and equal to the short-

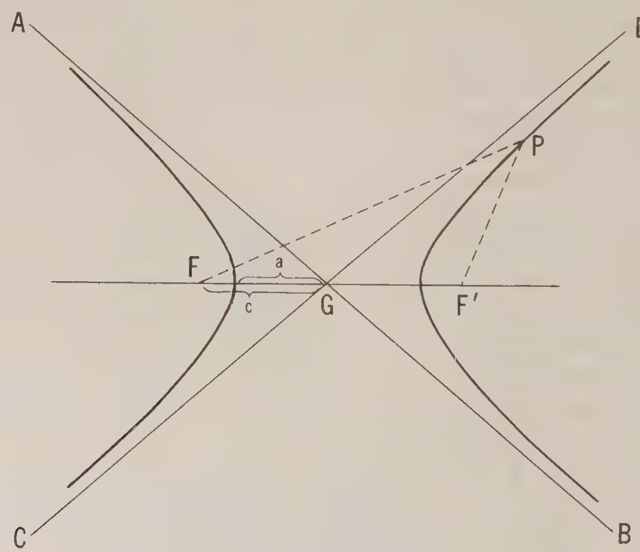

FIGURE O34d. A hyperbola.

est distance between the two branches. That is, $PF-PF'=2a$ (fig. O34d). The straight line through F and F' is called the **axis.** The **eccentricity** (*e*) of a hyperbola

is the ratio $\frac{c}{a}$ (fig. O34d). It is always greater than 1. Each branch of a hyperbola approaches ever closer to, but never reaches, a pair of intersecting straight lines, AB and CD, called **asymptotes.** These intersect at G.

The various conic sections bear an eccentricity relationship to each other. The eccentricity of a circle is 0, that of an ellipse is greater than 0 but less than 1, that of a parabola or straight line (a limiting case of a parabola) is 1, and that of a hyperbola is greater than 1.

If e=eccentricity, A=area, a=semimajor axis of an ellipse or half the shortest distance between the two branches of a hyperbola, b=the semiminor axis of an ellipse, and c=the distance between the center of an ellipse and one of its focal points or the distance between the focal point of a hyperbola and the intersection of its asymptotes:

Circle:
Eccentricity: $e=0$
Other relationships given in article O30.

Ellipse:
Area: $A=\pi ab$
Eccentricity: $e=\frac{c}{a}$, greater than 0, but less than 1.

Parabola:
Eccentricity: $e=1$.

Hyperbola:
Eccentricity: $e=\frac{c}{a}$, greater than 1.

When cones are intersected by some surface other than a plane, as the curved surface of the earth, the resulting sections do not follow the relationships given above, the amount of divergence therefrom depending upon the individual circumstances. Thus, a "hyperbolic" line of position (art. 1109) is not a true hyperbola.

O35. Spheres.—A **sphere** is a solid bounded by a surface every point of which is equidistant from a point within, called the **center.** It may be formed by rotating a circle about any diameter.

A **radius** or **semidiameter** of a sphere is a straight line connecting its center with any point on its surface. A **diameter** of a sphere is a straight line through its center and terminated at both ends by the surface of the sphere. The poles of a sphere are the ends of a diameter.

The intersection of a plane and the surface of a sphere is a circle, a **great circle** if the plane passes through the center of the sphere, and a **small circle** if it does not. The shorter arc of the great circle between two points on the surface of a sphere is the shortest distance, on the surface of the sphere, between the points. Every great circle of a sphere bisects every other great circle of that sphere. The **poles** of a circle on a sphere are the extremities of the sphere's diameter which is perpendicular to the plane of the circle. All points on the circumference of the circle are equidistant from either of its poles. In the case of a great circle, *both* poles are 90° from any point on the circumference of the circle. Any great circle may be considered a **primary,** particularly when it serves as the origin of measurement of a coordinate. The great circles through its poles are called **secondaries.** Secondaries are perpendicular to their primary.

A **spherical triangle** is the figure formed on the surface of a sphere by the intersection of three great circles. The lengths of the sides of a spherical triangle are measured in degrees, minutes, and seconds, as the angular lengths of the arcs forming them. The

sum of the three sides is always less than 360°. The sum of the three angles is always *more* than 180° and *less* than 540°.

A **lune** is that part of the surface of a sphere bounded by halves of two great circles.

A **spheroid** is a flattened sphere, which may be formed by rotating an ellipse about one of its axes. An **oblate spheroid,** such as the earth, is formed when an ellipse is rotated about its minor axis. In this case the diameter along the axis of rotation is less than the major axis. A **prolate spheroid** is formed when an ellipse is rotated about its major axis. In this case the diameter along the axis of rotation is greater than the minor axis.

If A=area, r=radius, d=diameter, and V=volume of a sphere:

$$\text{Area: } A=4\pi r^2=\pi d^2$$

$$\text{Volume: } V=\frac{4\pi r^3}{3}=\frac{\pi d^3}{6}$$

If A=area, a=semimajor axis, b=semiminor axis, e=eccentricity, and V=volume of an oblate spheroid:

$$\text{Area: } A=4\pi a^2\left(1-\frac{e^2}{3}-\frac{e^4}{15}-\frac{e^6}{35}-\cdots\right)$$

$$\text{Eccentricity: } e=\sqrt{\frac{a^2-b^2}{a^2}}$$

$$\text{Volume: } V=\frac{4\pi a^2 b}{3}$$

O36. Coordinates are magnitudes used to define a position. Many different types of coordinates are used.

If a position is known to be at a stated point, no magnitudes are needed to identify the position, although they may be required to locate the point. Thus, if a vessel is at port A, its position is known if the location of port A is known, but latitude and longitude may be needed to locate port A.

If a position is known to be on a given line, a single magnitude (coordinate) is needed to identify the position if an origin is stated or understood. Thus, if a vessel is known to be *south* of port B, it is known to be on a line extending southward from port B. If its distance from port B is known, and the position of port B is known, the position of the vessel is uniquely defined.

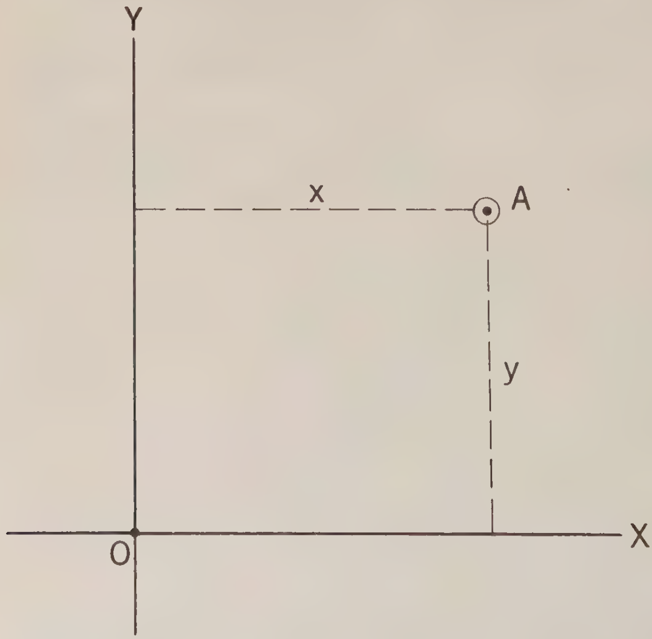

FIGURE O36a. Rectangular coordinates.

If a position is known to be on a given surface, two magnitudes (coordinates) are needed to define the position. Thus, if a vessel is known to be on the surface of the earth, its position can be identified by means of latitude and longitude. Latitude indicates its angular distance north or south of the equator, and longitude its angular distance east or west of the prime meridian.

If nothing is known regarding a position other than that

it exists in space, three magnitudes (coordinates) are needed to define its position. Thus, the position of a submarine may be defined by means of latitude, longitude, and depth below the surface.

Each coordinate requires an origin, either stated or implied. If a position is known to be on a given plane, it might be defined by means of its distance from each of two intersecting lines, called **axes.** Thus, in figure O36a the position of point A can be defined by stating that it is x units to the right of line OY and y units upward from line OX. These are called **rectangular coordinates.** The coordinate along OY is called the **ordinate,** and the coordinate along OX is called the **abscissa.** Point O is the **origin,** and lines OX and OY the **axes** (called the X and Y axes, respectively). Point A is at position x, y. If the axes are not perpendicular but the lines x and y are drawn parallel to the axes, **oblique coordinates** result. Either type are **Cartesian coordinates.** A three-dimensional system of Cartesian coordinates, with X, Y, and Z axes, is called **space coordinates.**

Another system of plane coordinates in common usage consists of the *direction* and *distance* from the origin (called the **pole**), as shown in figure O36b. A line extending in the direction indicated is called a **radius vector.** Direction and distance from a fixed point constitute **polar coordinates,** sometimes called the rho- (the Greek ρ, to indicate distance) theta (the Greek θ, to indicate direction) system. Navigators more commonly call it the "bearing-distance" system. An example of its use is with respect to a radar PPI (art. 1208).

Spherical coordinates are used to define a position on the surface of a sphere or spheroid by indicating angular distance from a primary great circle and a reference secondary great circle. Familiar examples are latitude and longitude, altitude and azimuth, and declination and hour angle.

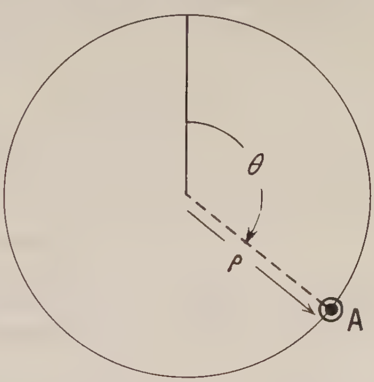

FIGURE O36b. Polar coordinates.

Trigonometry

O37. Definitions.—Trigonometry is that branch of mathematics dealing with the relations among the angles and sides of triangles. **Plane trigonometry** is that branch dealing with plane triangles, and **spherical trigonometry** is that branch dealing with spherical triangles.

O38. Angular measure.—A circle may be divided into 360 **degrees** (°), which is the **angular length** of its circumference. Each degree may be divided into 60 **minutes** (′), and each minute into 60 **seconds** (″). The angular length of an arc is usually expressed in these units. By this system a right angle or quadrant has 90° and a straight angle or semicircle 180°. In marine navigation, altitudes, latitudes, and longitudes are usually expressed in degrees, minutes, and tenths (27°14′.4). Azimuths are usually expressed in degrees and tenths (164°.7). The system of degrees, minutes, and seconds indicated above is the **sexagesimal system.** In the **centesimal system,** used chiefly in France, the circle is divided into 400 **centesimal degrees** (sometimes called **grades**) each of which is divided into 100 **centesimal minutes** of 100 **centesimal seconds** each.

A **radian** is the angle subtended at the center of a circle by an arc having a linear length equal to the radius of the circle. A radian is equal to 57°.2957795131 approximately, or 57°17′44″.80625 approximately. The radian is sometimes used as a unit of angular measure. A circle (360°) $=2\pi$ radians, a semicircle (180°) $=\pi$ radians, a right angle (90°) $=\frac{\pi}{2}$ radians, 1° $=0.0174532925$ radians approximately, 1′ $=0.0002908882$ radians approximately, and 1″ $=0.0000048481$ radians approximately.

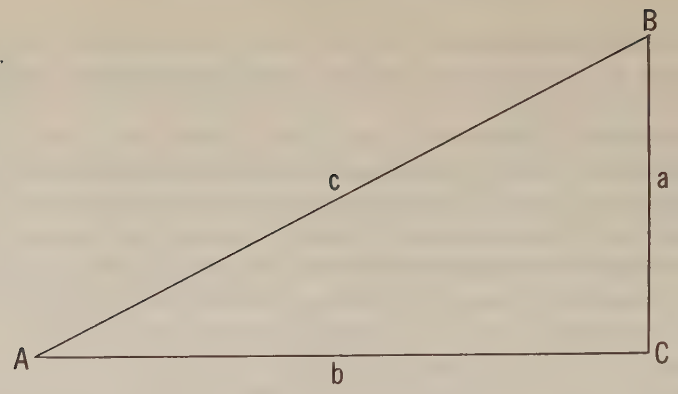

FIGURE O39a. A right triangle.

O39. Trigonometric functions are the various proportions or ratios of the sides of a plane right triangle, defined in relation to one of the acute angles. In figure O39a, A, B, and C are the angles of a plane right triangle, the right angle being at C. The sides are a, b, c, as shown. The six principal trigonometric functions of angle A are:

$$\text{sine } A = \sin A = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{a}{c}$$

$$\text{cosine } A = \cos A = \frac{\text{side adjacent}}{\text{hypotenuse}} = \frac{b}{c}$$

$$\text{tangent } A = \tan A = \frac{\text{side opposite}}{\text{side adjacent}} = \frac{a}{b}$$

$$\text{cotangent } A = \cot A = \frac{\text{side adjacent}}{\text{side opposite}} = \frac{b}{a}$$

$$\text{secant } A = \sec A = \frac{\text{hypotenuse}}{\text{side adjacent}} = \frac{c}{b}$$

$$\text{cosecant } A = \csc A = \frac{\text{hypotenuse}}{\text{side opposite}} = \frac{c}{a}.$$

Certain additional relations are also classed as trigonometric functions:

versed sine A=versine A=vers A=ver $A=1-\cos A$

versed cosine A=coversed sine A=coversine A=covers A=cov $A=1-\sin A$

haversine A=hav $A=\frac{1}{2}$ ver $A=\frac{1}{2}(1-\cos A)$.

The numerical value of a trigonometric function is sometimes called the **natural function** to distinguish it from the logarithm of the function, called the **logarithmic function.** Numerical values of the six principal functions are given at 1′ intervals in table 31. Logarithms are given at the same intervals in table 33. Both natural and logarithmic haversines are given in table 34.

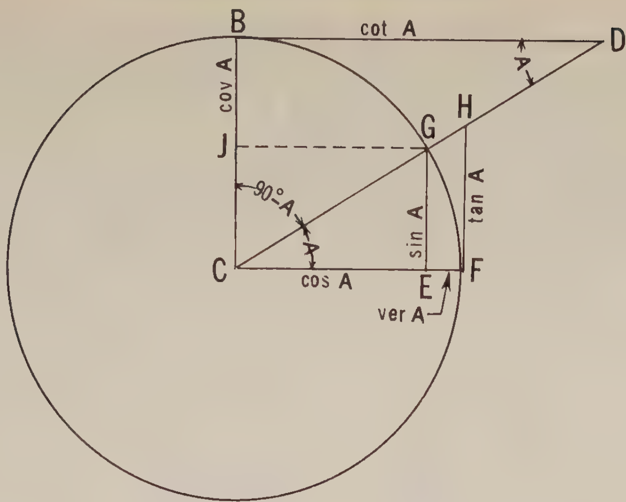

FIGURE O39b. Line definitions of trigonometric functions.

Various functions may be represented by lines associated with a circle, as shown in figure O39b. The radius of the circle is considered 1. Angle BDC=angle ECG=angle A.

$\sin A=GE$	$\cot A=BD$
$\cos A=CE$	$\sec A=CH$
$\tan A=HF$	$\csc A=CD$
$\text{ver } A=EF$	$\text{cov } A=BJ.$

Some relationships apply only to plane trigonometry and others to both plane and spherical trigonometry. Those which apply to both are called **fundamental identities.** Examples are given below.

Of the six principal functions, the second three are the reciprocals of the first three. Thus,

$$\sin A=\frac{1}{\csc A} \qquad \csc A=\frac{1}{\sin A}$$

$$\cos A=\frac{1}{\sec A} \qquad \sec A=\frac{1}{\cos A}$$

$$\tan A=\frac{1}{\cot A} \qquad \cot A=\frac{1}{\tan A}$$

From figure O39a:

$$\sin B=\frac{b}{c}=\cos A \qquad \cot B=\frac{a}{b}=\tan A$$

$$\cos B=\frac{a}{c}=\sin A \qquad \sec B=\frac{c}{a}=\csc A$$

$$\tan B=\frac{b}{a}=\cot A \qquad \csc B=\frac{c}{b}=\sec A.$$

Since A and B are *complementary*, these relations show that the sine of an angle is the cosine of its complement, the tangent of an angle is the cotangent of its complement, and the secant of an angle is the cosecant of its complement. Thus, the **co** function of an angle is the function of its **co**mplement.

O40. The functions in various quadrants.—The sign (+ or −) of the functions varies with the quadrant of an angle. This is shown in figure O40a. In the left-hand diagram a radius is imagined to rotate in a counterclockwise direction through 360°

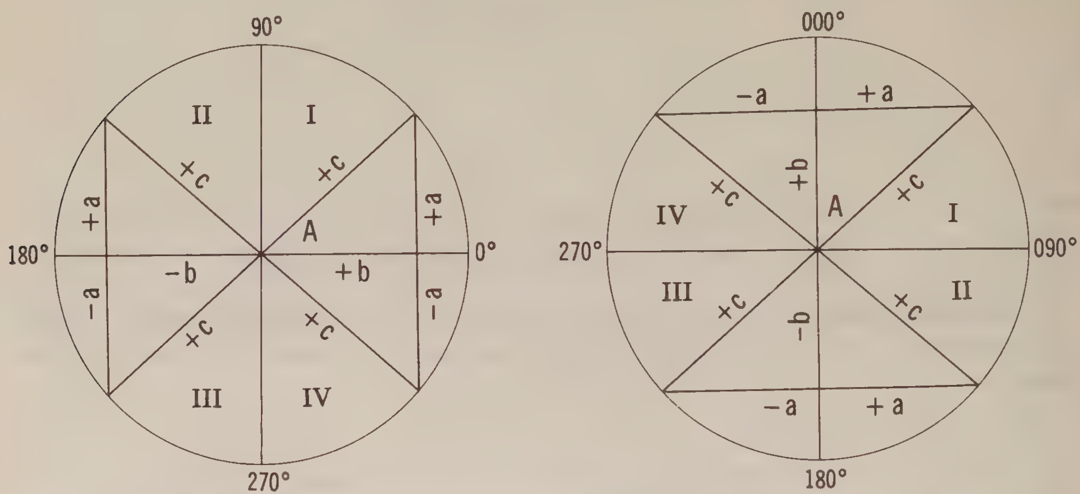

FIGURE O40a. Trigonometric functions in the four quadrants. *Left*, mathematical convention; *right*, navigational convention.

from the horizontal position at 0°. This is the mathematical convention. In the right-hand figure this concept is shown in the usual navigational convention of a compass rose, starting with 000° at the top and rotating clockwise. In either diagram the angle A between the original position of the radius and its position at any time increases from 0° to 90° in the *first quadrant* (I), 90° to 180° in the *second quadrant* (II), 180° to 270° in the *third quadrant* (III), and 270° to 360° in the *fourth quadrant* (IV). If the values of a and b are considered positive in the directions they extend in the first quadrant (*upward* and to the *right*) and negative in the opposite directions, and if c is regarded as always positive, the signs of the functions can be determined by considering the signs of the sides involved, as shown in the following table:

Functions	I	II	III	IV
sine and cosecant	+	+	−	−
cosine and secant	+	−	−	+
tangent and cotangent	+	−	+	−
versine, coversine, and haversine	+	+	+	+

TABLE O40a. Signs of trigonometric functions by quadrant.

The numerical values vary as shown in the following table and in figure O40b:

Functions	I	II	III	IV
sine cosecant	0 to +1 $+\infty$ to +1	+1 to 0 +1 to $+\infty$	0 to −1 $-\infty$ to −1	−1 to 0 −1 to $-\infty$
cosine secant	+1 to 0 +1 to $+\infty$	0 to −1 $-\infty$ to −1	−1 to 0 −1 to $-\infty$	0 to +1 $+\infty$ to +1
tangent cotangent	0 to $+\infty$ $+\infty$ to 0	$-\infty$ to 0 0 to $-\infty$	0 to $+\infty$ $+\infty$ to 0	$-\infty$ to 0 0 to $-\infty$
versine coversine haversine	0 to +1 +1 to 0 0 to $+\frac{1}{2}$	+1 to +2 0 to +1 $+\frac{1}{2}$ to +1	+2 to +1 +1 to +2 +1 to $+\frac{1}{2}$	+1 to 0 +2 to +1 $+\frac{1}{2}$ to 0

TABLE O40b. Values of trigonometric functions in various quadrants. These relationships are shown graphically in figure O40b.

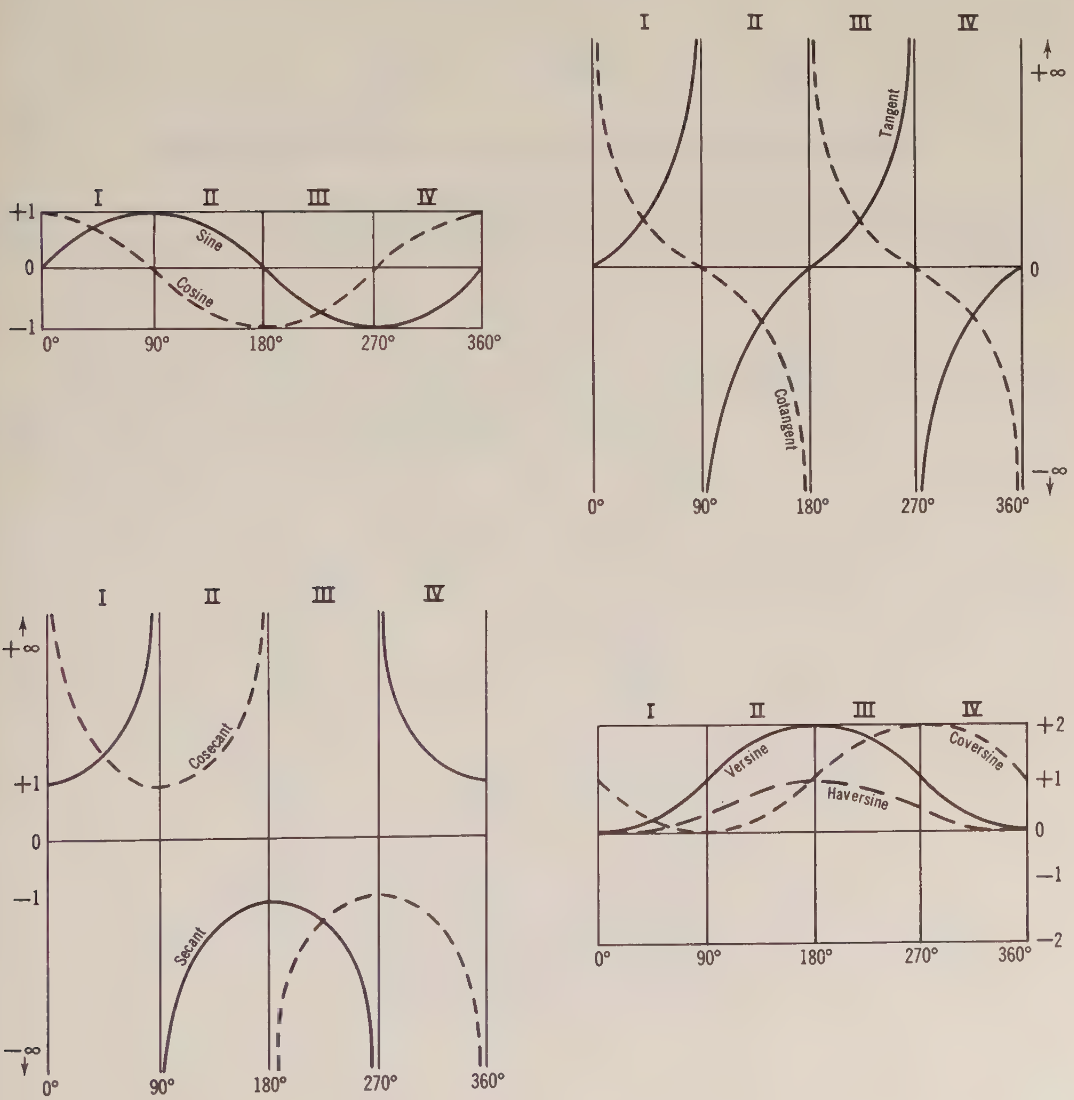

FIGURE O40b. Graphic representation of values of trigonometric functions in various quadrants.

The functions of any angle in the second, third, and fourth quadrants are numerically equal to the same functions of some angle in the first quadrant, as follows:

Quadrant	*Corresponding angle in first quadrant*
II	180°—angle
III	angle—180°
IV	360°—angle.

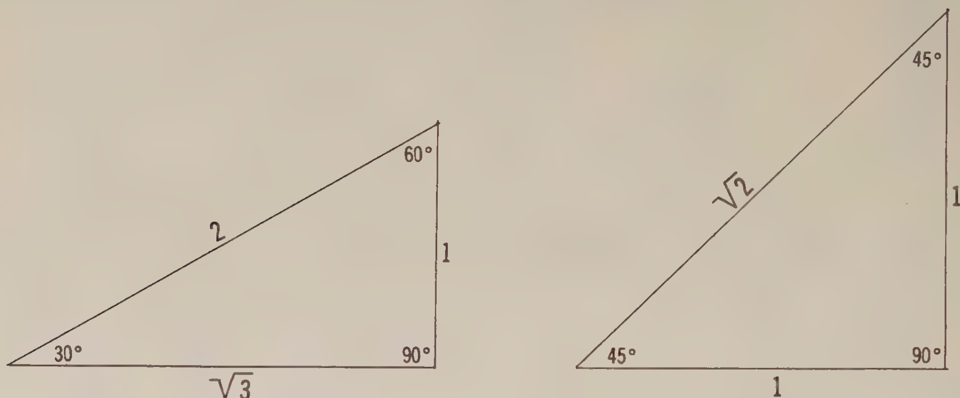

FIGURE O40c. Numerical relationship of sides of 30°-60° and 45° triangles.

Since the relationships of 30°-60° and 45° right triangles are as shown in figure O40c, certain values of the basic functions can be stated exactly as shown in the following table:

Function	*30°*	*45°*	*60°*
sine	$\frac{1}{2}$	$\frac{1}{\sqrt{2}}=\frac{1}{2}\sqrt{2}$	$\frac{\sqrt{3}}{2}=\frac{1}{2}\sqrt{3}$
cosine	$\frac{\sqrt{3}}{2}=\frac{1}{2}\sqrt{3}$	$\frac{1}{\sqrt{2}}=\frac{1}{2}\sqrt{2}$	$\frac{1}{2}$
tangent	$\frac{1}{\sqrt{3}}=\frac{1}{3}\sqrt{3}$	$\frac{1}{1}=1$	$\frac{\sqrt{3}}{1}=\sqrt{3}$
cotangent	$\frac{\sqrt{3}}{1}=\sqrt{3}$	$\frac{1}{1}=1$	$\frac{1}{\sqrt{3}}=\frac{1}{3}\sqrt{3}$
secant	$\frac{2}{\sqrt{3}}=\frac{2}{3}\sqrt{3}$	$\frac{\sqrt{2}}{1}=\sqrt{2}$	$\frac{2}{1}=2$
cosecant	$\frac{2}{1}=2$	$\frac{\sqrt{2}}{1}=\sqrt{2}$	$\frac{2}{\sqrt{3}}=\frac{2}{3}\sqrt{3}$

TABLE O40c. Values of various trigonometric functions for angles of 30°, 45°, and 60°.

O41. Inverse trigonometric functions.—The angle having a given trigonometric function may be indicated in any of several ways. Thus, sin $y=x$, $y=\text{arc sin } x$, and $y=\sin^{-1} x$ have the same meaning. The superior -1 is not an exponent in this case. In each case, y is "the angle whose sine is x." In this case, y is the **inverse sine** of x. Similar relationships hold for all trigonometric functions.

O42. Solution of triangles.—A triangle is composed of six parts: three angles and three sides. The angles may be designated A, B, and C; and the sides opposite these angles as a, b, and c, respectively. In general, when three parts are known, the other three parts can be found, unless the known parts are the three angles of a plane triangle.

Right plane triangles.—In a right plane triangle it is only necessary to substitute numerical values in the appropriate formulas representing the basic trigonometric functions (art. O39) and solve. Thus, if a and b are known:

$$\tan A=\frac{a}{b}$$

$$B=90°-A$$

$$c=a \csc A.$$

Similarly, if c and B are given:

$$A=90°-B$$

$$a=c \sin A$$

$$b=c \cos A.$$

Oblique plane triangles.—In solving an oblique plane triangle, it is often desirable to draw a rough sketch of the triangle approximately to scale, as shown in figure O42a. The following laws are helpful in solving such triangles:

Law of sines: $\dfrac{a}{\sin A}=\dfrac{b}{\sin B}=\dfrac{c}{\sin C}$

Law of cosines: $a^2=b^2+c^2-2\ bc \cos A.$

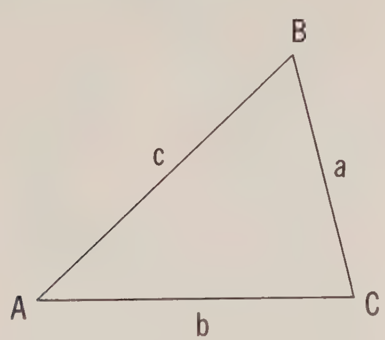

FIGURE O42a. A plane oblique triangle.

The unknown parts of oblique plane triangles can be computed by the formulas of table O42a, among others. By reassignment of letters to sides and angles, these formulas can be used to solve for all unknown parts of oblique plane triangles.

Known	*To find*	*Formula*	*Comments*
a, b, c	A	$\cos A = \frac{c^2+b^2-a^2}{2\,bc}$	Cosine law
a, b, A	B	$\sin B = \frac{b \sin A}{a}$	Sine law. Two solutions if $b>a$
	C	$C=180°-(A+B)$	$A+B+C=180°$
	c	$c=\frac{a \sin C}{\sin A}$	Sine law
a, b, C	A	$\tan A=\frac{a \sin C}{b-a \cos C}$	
	B	$B=180°-(A+C)$	$A+B+C=180°$
	c	$c=\frac{a \sin C}{\sin A}$	Sine law
a, A, B	b	$b=\frac{a \sin B}{\sin A}$	Sine law
	C	$C=180°-(A+B)$	$A+B+C=180°$
	c	$c=\frac{a \sin C}{\sin A}$	Sine law

TABLE O42a. Formulas for solving oblique plane triangles.

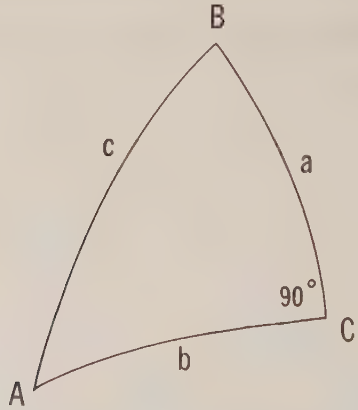

FIGURE O42b. Parts of a right spherical triangle as used in Napier's rules.

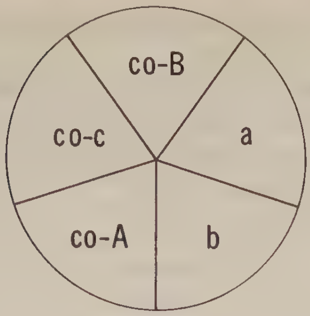

FIGURE O42c. Diagram for Napier's rules.

Right spherical triangles can be solved with the aid of **Napier's rules,** devised by John Napier. If the right angle is omitted, the triangle has five parts: two angles and three sides, as shown in figure O42b. The triangle can be solved if any two parts are known. If the two sides forming the right angle, and the *complements* of the other three parts are used, these elements (called "parts" in the rules) can be arranged in five sectors of a circle in the same order in which they occur in the triangle, as shown in figure O42c. Considering *any* part as the *middle* part, the two parts nearest it in the diagram are considered the *adjacent* parts, and the two farthest from it the *opposite* parts. The rules are:

The sine of a middle part equals the product of (1) the tangents of the adjacent parts or (2) the cosines of the opposite parts.

In the use of these rules, the *co* function of a complement can be given as the function of the element. Thus, the cosine of co-A is the same as the sine of A. From these rules the following formulas can be derived:

$$\sin a = \tan b \cot B = \sin c \sin A$$
$$\sin b = \tan a \cot A = \sin c \sin B$$
$$\cos c = \cot A \cot B = \cos a \cos b$$
$$\cos A = \tan b \cot c = \cos a \sin B$$
$$\cos B = \tan a \cot c = \cos b \sin A.$$

The following rules apply:

1. An oblique angle and the side opposite are in the same quadrant.
2. Side c (the hypotenuse) is less than 90° when a and b are in the same quadrant, and more than 90° when a and b are in different quadrants.

If the known parts are an angle and its opposite side, two solutions are possible.

A **quadrantal spherical triangle** is one having one side of 90°. A **biquadrantal spherical triangle** has two sides of 90°. A **triquadrantal spherical triangle** has three sides of 90°. A biquadrantal spherical triangle is isosceles and has two right angles opposite the 90° sides. A triquadrantal spherical triangle is equilateral, has three right angles, and bounds an octant (one-eighth) of the surface of the sphere. A quadrantal spherical triangle can be solved by Napier's rules provided any two elements in addition to the 90° side are known. The 90° side is omitted and the other parts are arranged in order in a five-sectored circle, using the complements of the three parts farthest from the 90° side. In the case of a quadrantal triangle, rule 1 above is used, and rule 2 restated: angle C (the angle opposite the side of 90°) is *more* than 90° when A and B are in the same quadrant, and *less* than 90° when A and B are in different quadrants. If the

rule requires an angle of more than 90° and the solution produces an angle of less than 90°, subtract the solved angle from 180°.

Oblique spherical triangles. An oblique spherical triangle can be solved by dropping a perpendicular from one of the apexes to the opposite side, extended if necessary, to form two right spherical triangles. It can also be solved by the following formulas, reassigning the letters as necessary.

Known	*To find*	*Formula*	*Comments*
a, b, c	A	$\text{hav } A = \dfrac{\text{hav } a - \text{hav }(b-c)}{\sin b \sin c}$

TABLE O42b. Formulas for solving oblique spherical triangles.

Calculus

O43. Definitions.—**Calculus** is that branch of mathematics dealing with the rate of change of one quantity with respect to another.

A **constant** is a quantity which does not change. If a vessel is making good a course of 090°, the latitude does not change and is therefore a constant.

A **variable,** where continuous, is a quantity which can have an infinite number of values, although there may be limits to the maximum and minimum. Thus, from latitude 30° to latitude 31° there are an infinite number of latitudes, if infinitesimally small units are taken, but no value is less than 30° nor more than 31°. If two variables are so related that for every value of one there is a corresponding value of the other, one of the values is known as a **function** of the other. Thus, if speed is constant, the distance a vessel steams depends upon the elapsed time. Since elapsed time does not depend upon any other quantity, it is called an **independent variable.** The distance depends upon the elapsed time, and therefore is called a **dependent variable.** If it is required to find the time needed to travel any given distance at constant speed, distance is the independent variable and time is the dependent variable.

The principal processes of calculus are differentiation and integration.

O44. Differentiation is the process of finding the rate of change of one variable with respect to another. If x is an independent variable, y is a dependent variable, and y is a function of x, this relationship may be written $y=f(x)$. Since for every value of x there is a corresponding value of y, the relationship can be plotted as a curve, figure O44. In this figure, A and B are any two points on the curve, a short distance apart.

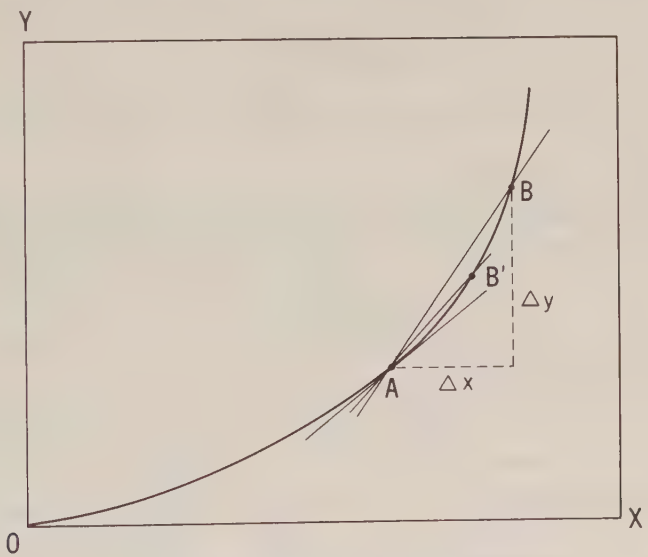

FIGURE O44. Differentiation.

The difference between the value of x at A and at B is Δx (delta x), and the corresponding difference in the value of y is Δy (delta y). The straight line through points A and B is a **secant** of the curve (art. O30). It represents the rate of change between A and B, for anywhere along this line the change of y is proportional to the change of x.

As B moves closer to A, as shown at B', both Δx and Δy become smaller, but at a different rate, and $\frac{\Delta y}{\Delta x}$ changes. This is indicated by the difference in the slope of the secant. Also, that part of the secant between A and B moves closer to the curve and becomes a better approximation of it. The limiting case occurs when B reaches A or is at an infinitesimal distance from it. As the distance becomes infinitesimal, both Δy and Δx become infinitely small, and are designated dy and dx, respectively. The straight line becomes tangent to the curve, and represents the rate of change, or slope, of the curve at that point. This is indicated by the expression $\frac{dy}{dx}$, called the **derivative** of y with respect to x.

The process of finding the value of the derivative is called **differentiation.** It depends upon the ability to connect x and y by an equation. For instance, if $y=x^n$, $\frac{dy}{dx}=nx^{n-1}$. If $n=2$, $y=x^2$, and $\frac{dy}{dx}=2x$. This is derived as follows: If point A on the curve is x, y; point B can be considered $x+\Delta x, y+\Delta y$. Since the relation $y=x^2$ is true anywhere on the curve, at B:

$$y+\Delta y=(x+\Delta x)^2=x^2+2x\Delta x+(\Delta x)^2.$$

Since $y=x^2$, and equal quantities can be subtracted from both sides of an equation without destroying the equality:

$$\Delta y=2x\Delta x+(\Delta x)^2.$$

Dividing by Δx:

$$\frac{\Delta y}{\Delta x}=2x+\Delta x.$$

As B approaches A, Δx becomes infinitesimally small, approaching 0 as a limit. Therefore $\frac{\Delta y}{\Delta x}$ approaches $2x$ as a limit.

This can be demonstrated by means of a numerical example. Let $y=x^2$. Suppose at A, $x=2$ and $y=4$, and at B, $x=2.1$ and $y=4.41$. In this case $\Delta x=0.1$ and $\Delta y=0.41$, and

$$\frac{\Delta y}{\Delta x}=\frac{0.41}{0.1}=4.1.$$

From the other side of the equation:

$$2x+\Delta x=2\times 2+0.1=4.1.$$

If Δx is 0.01 and Δy is 0.0401, $\frac{\Delta y}{\Delta x}=4.01$. If Δx is 0.001, $\frac{\Delta y}{\Delta x}=4.001$; and if Δx is 0.0001, $\frac{\Delta y}{\Delta x}=4.0001$. As Δx approaches 0 as a limit, $\frac{\Delta y}{\Delta x}$ approaches 4, which is therefore the value $\frac{dy}{dx}$. Therefore, at point A the *rate* of change of y with respect to x is 4, or y is increasing in value 4 times as fast as x.

An example of the use of differentiation in navigation is the Δd value in H.O. Pub. No. 214. This is the change of altitude for a change of 1′ of declination. In this case, declination is the independent variable, altitude is the dependent variable, and both meridian angle (H.A.) and latitude are constants. The rate of change at the tabulated value is desired, so that the table can be entered with the *nearest* tabulated

value of declination, and interpolation performed in either direction (either larger or smaller values of declination).

O45. Integration is the inverse of differentiation. Unlike the latter, however, it is not a direct process, but involves the recognition of a mathematical expression as the differential of a known function. The function sought is the **integral** of the given expression. Most functions can be differentiated, but many cannot be integrated.

Integration can be considered the summation of an infinite number of infinitesimally small quantities, between specified limits. Consider, for instance, the problem of finding an area below a specified part of a curve for which a mathematical expression can be

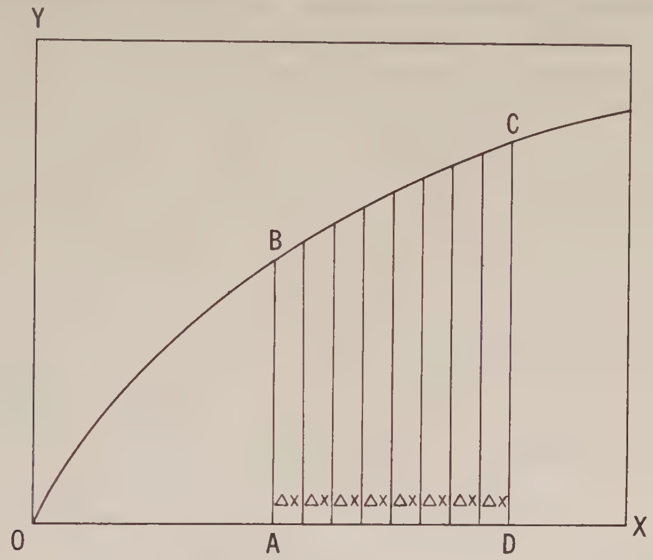

FIGURE O45. Integration.

written. Suppose it is desired to find the area *ABCD* of figure O45. If vertical lines are drawn dividing the area into a number of vertical strips, each Δx wide, and if y is the height of each strip at the midpoint of Δx, the area of each strip is approximately $y\Delta x$; and the approximate total area of all strips is the sum of the areas of the individual strips. This may be written $\sum_{x_1}^{x_2} y\Delta x$, meaning the sum of all $y\Delta x$ values between x_1 and x_2. The symbol $\sum$ is the Greek letter *sigma*, the equivalent of the English *S*. If Δx is made progressively smaller, the sum of the small areas becomes ever closer to the true total area. If Δx becomes infinitely small, the summation expression is written $\int_{x_1}^{x_2} ydx$, the symbol dx denoting an infinitely small Δx. The symbol $\int$, called the "integral sign," is a distorted *S*.

An expression such as $\int_{x_1}^{x_2} ydx$ is called a **definite integral** because limits are specified (x_1 and x_2). If limits are not specified, as in $\int ydx$, the expression is called an **indefinite integral.**

A navigational application of integration is the finding of meridional parts, table 5. The *rate* of change of meridional parts with respect to latitude changes progressively. The formula given in the explanation of the table is the equivalent of an integral representing the sum of the meridional parts from the equator to any given latitude.

O46. Differential equations.—An expression such as dy or dx is called a **differential.** An equation involving a differential or a derivative is called a **differential equation.**

As shown in article O44, if $y=x^2$, $\frac{dy}{dx}=2x$. Neither dy nor dx is a finite quantity, but both are *limits* to which Δy and Δx approach as they are made progressively smaller. Therefore $\frac{dy}{dx}$ is merely a ratio, the limiting value of $\frac{\Delta y}{\Delta x}$, and not one finite number divided by another. However, since the ratio is the same as would be obtained by using finite quantities, it is possible to use the two differentials dy and dx independently in certain relationships. Differential equations involve such relationships.

APPENDIX P

INTERPOLATION

P1. Introduction.—If one quantity varies with changing values of a second quantity, and the mathematical relationship of the two is known, a curve can be drawn to represent the values of one corresponding to various values of the other. To find the value of either quantity corresponding to a given value of the other, one finds that point on the curve defined by the given value, and reads the answer on the scale relating to the other quantity. This assumes, of course, that for each value of one quantity, there is only one value of the other quantity.

Information of this kind can also be tabulated. Each entry represents one point on the curve. The finding of a value *between* tabulated entries is called **interpolation.** The extending of tabulated values to find values *beyond* the limits of the table is called **extrapolation.**

Thus, the *Nautical Almanac* tabulates values of declination of the sun for each hour of Greenwich mean time. The finding of declination for a time between two whole hours requires interpolation. Since there is only one entering **argument** (in this case GMT), **single interpolation** is involved.

Table 19 gives the distance traveled in various times at certain speeds. In this table there are two entering arguments. If both given values are between tabulated values, **double interpolation** is needed.

In H.O. Pub. No. 214, azimuth angle varies with a change in any of the three variables latitude, declination, and meridian angle. With intermediate values of all three, **triple interpolation** is needed.

Interpolation can sometimes be avoided. A table having a single entering argument can be arranged as a **critical table.** An example is the dip (height of eye) correction on the inside front cover of the *Nautical Almanac*. In such a table limiting values of the entering argument are given. Another way of avoiding interpolation would be to include every possible entering argument. If this were done for H.O. Pub. No. 214, interpolation being eliminated for declination only, and assuming declination values to 0.′1, the number of volumes would be increased from nine to more than 5,000. If interpolation for meridian angle and latitude, to 0.′1, were also to be avoided, a total of more than 1,800,000,000 volumes would be needed. A more practical method is to select an assumed position to avoid the need for interpolation for two of the variables. For stars, which change declination slowly, interpolation for the third argument can be avoided by using values for the declination of each body in the preparation of the table, as in H.O. Pub. No. 249, volume I. Another way of avoiding interpolation is to portray the information graphically. Still another way is to solve the appropriate equation each time a value is needed.

Notwithstanding all these available devices, the need for interpolation is frequently encountered in navigation. The person who thoroughly understands it is least likely to make mistakes in its use.

P2. Single interpolation.—The accurate determination of intermediate values requires knowledge of the nature of the change between tabulated values. The simplest relationship is **linear,** the change in the tabulated value being directly proportional to

the change in the entering argument. Thus, if a vessel is proceeding at 15 knots, the distance traveled is directly proportional to the time, as shown in figure P2a. The same information might be given in tabular form, as shown in table P2a. Mathematically, this relationship is written $D=\frac{15t}{60}=\frac{t}{4}$, where D is distance in nautical miles, and t is time in minutes.

In such a table, interpolation can be accomplished by simple proportion. Suppose, for example, that the distance is desired for a time of 15 minutes. It will be some

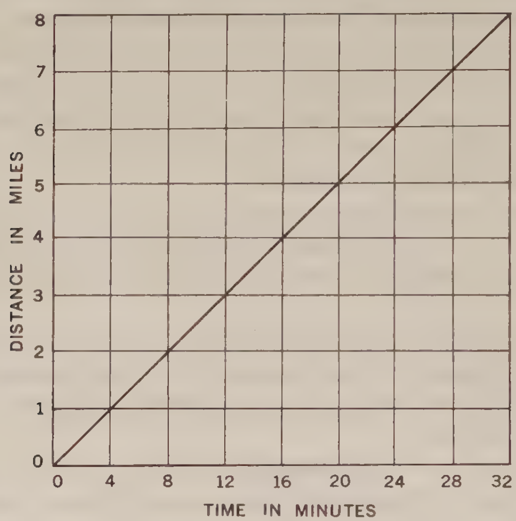

FIGURE P2a. Plot of $D=\frac{t}{4}$.

24	6. 0
28	7. 0
32	8. 0

TABLE P2a. Table of $D=\frac{t}{4}$.

value between 3.0 and 4.0 miles, because these are the distances for 12 and 16 minutes, respectively, the tabulated times on each side of the desired time. The proportion might be formed as follows:

$$\begin{array}{lll} & 12 & \\ 3 & & \\ & 15 & 4 \\ & 16 & \end{array} \qquad\qquad \begin{array}{lll} & 3.0 & \\ x & & \\ & y & 1.0 \\ & 4.0 & \end{array}$$

$$\frac{3}{4}=\frac{x}{1.0}$$

$$x=\frac{3\times 1.0}{4}=0.75 \text{ (0.8 to nearest 0.1 mi.)}$$

$$y=3.0+x=3.0+0.8=3.8 \text{ mi.}$$

A simple interpolation such as this should be performed mentally. During the four-minute interval between 12 and 16 minutes, the distance *increases* 1.0 mile from 3.0 to 4.0 miles. At 15 minutes, ¾ of the interval has elapsed, and so the distance increases ¾ of 1.0 mile, or 0.75 mile, and is therefore 3.0+0.8=3.8, to the nearest 0.1 mile.

This might also have been performed by starting with 16 minutes, as follows:

$$1\left[\begin{array}{c|c} 12 & \\ 15 & 4 \\ 16 & \end{array}\right] \qquad\qquad (-)x\left[\begin{array}{c|c} 3.0 & \\ y & 1.0 \\ 4.0 & \end{array}\right]$$

$$\frac{1}{4}=\frac{(-)x}{1.0}$$

$x=(-)0.25$ (-0.2 to the nearest 0.1 mi.)

$y=4.0-0.2=3.8$

Mentally, 15 is one quarter of the way from 16 to 12, and therefore the distance is ¼ the way between 4.0 and 3.0, or 3.8.

This interpolation might have been performed by noting that if distance changes 1.0 mile in four minutes, it must change $\frac{1.0}{10}=0.1$ mile in $\frac{4}{10}=0.4$ minute, or 24 seconds. This relationship can be used for mental interpolation in situations which might seem to require pencil and paper. Thus, if distance to the nearest 0.1 mile is desired for $13^{m}15^{s}$, the answer is 3.3 miles, determined as follows: The time $13^{m}15^{s}$ is $1^{m}15^{s}$ ($1^{m}.2$ approx.) more than 12^{m}. If 1.2 is divided by 0.4, the quotient is 3, to the nearest whole number. Therefore, $3\times0.1=0.3$ is added to 3, the tabulated value for 12 minutes. Alternatively, $13^{m}15^{s}$ is $2^{m}45^{s}$ ($2^{m}.8$ approx.) less than 16^{m}, and $2.8\div0.4=7$, and therefore the interpolated value is $7\times0.1=0.7$ *less* than 4, the tabulated value for 16^{m}. In either case, the interpolated value is 3.3 miles.

A common mistake in single interpolation is to apply the correction (x) with the wrong sign, particularly when it should be negative ($-$). This mistake can be avoided by always checking to be certain that the interpolated value lies between the two values used in the interpolation.

When the curve representing the values of a table is a straight line, as in figure P2a, the process of finding intermediate values in the manner described above is called **linear interpolation.** If tabulated values of such a line are exact (not approximations), as in table P2a, the interpolation can be carried to any degree of precision without sacrificing accuracy. Thus, in 21.5 minutes the distance is $5.0+\frac{1.5}{4}\times1.0=5.375$ miles. Similarly, for 29.9364 minutes the distance is $7.0+\frac{1.9364}{4}\times1.0=7.4841$ miles, a value which has little or no significance in practical navigation. If one had occasion to find such a value, it could most easily be done by dividing the time, in minutes, by 4, since the distance increases at the rate of one mile each four minutes. This would be a case of avoiding interpolation by solving the equation connecting the two quantities. For a simple relationship such as that involved here, such a solution might be easier than interpolation.

Many of the tables of navigation are not linear. Consider figure P2b. From table 29 it is found that for latitude 25° and declination 8°, same name, the variation of altitude in one minute of time from meridian transit (the altitude factor) is $6''.0$ ($0'.1$). For a limited angular distance on each side of the celestial meridian, the change in altitude is approximately equal to at^2, where a is the altitude factor (from table 29)

and t is the time in minutes from meridian transit. Figure P2b is the plot of change in altitude against time. The same information is shown in tabular form in table P2b.

To be strictly accurate in interpolating in such a table, one should consider the curvature of the line. However, in most navigational tables the points on the curve selected for tabulation are sufficiently close that the portion of the curve between entries can be considered a straight line without introducing a significant error. This is similar to considering the line of position from a celestial observation as a part of the circle of equal altitude. Thus, to the nearest 0.′1, the change of altitude for 3.4 minutes is $0.'9+(0.4\times0.'7)=0.'9+0.'3=1.'2$. The correct value by solution of the formula is 1.′156. The value for 6.8 minutes is 4.′6 by interpolation and 4.′624 by computation.

If the *direction* of curvature of the curve changes between entering arguments, an erroneous result might be obtained. Thus, in H.O. Pub. No. 214, the tabulated altitude for latitude 53° and meridian angle 0° is 89°30.′0 for declination 52°30′ same name, and 89°00.′0 for declination 54°00′ same name, the next entry. By

8	6. 4

TABLE P2b. Table of altitude change=at^2, where $a=0.'1$

linear interpolation for declination 53° same name the altitude is 89°20.′0. The correct value is 90°00.′0. Between declination 52°30′ and 53°00′ the altitude increases to 90°00.′0 and then decreases as declination increases. Such instances are infrequent in navigation, and generally occur at a part of the table that is not commonly used, or for which special provisions are made.

P3. Double interpolation.—In a double-entry table it may be necessary to interpolate for each entering argument. Table P3a is an extract from table 27 (amplitudes). If one entering argument is an exact tabulated value, the amplitude can be found by single interpolation. For instance, if latitude is 45° and declination is 21.°8, amplitude is $31.^\circ2+\left(\frac{3}{5}\times0.^\circ8\right)=31.^\circ2+0.^\circ5=31.^\circ7$. However, if neither entering argument is a tabulated value, double interpolation is needed. This may be accomplished in any of several ways:

Lat.	*Declination*	
	21.°5	22.°0
°	°	°
45	31. 2	32. 0
46	31. 8	32. 6

TABLE P3a. Excerpts from amplitude table.

1. *"Horizontal" method.* Use single interpolation for declination for each tabulated value of latitude, followed by single interpolation for latitude. Suppose latitude is 45°7 and declination is 21°8. First, find the amplitude for latitude 45°, declination 21°8, as above, 31°7. Next, repeat the process for latitude 46°: $31°8+\left(\frac{3}{5}\times 0°8\right)=32°3$. Finally, interpolate between 31°7 and 32°3 for latitude 45°7: $31°7+(0.7\times 0°6)=32°1$. This is the equivalent of first inserting a new column for declination 21°8, followed by single interpolation in this column, as shown in table P3b.

Lat.	*Declination*		
	21°5	*21°8*	22°0
°	°	°	°
45	31.2	*31.7*	32.0
45.7		***32.1***	
46	31.8	*32.3*	32.6

TABLE P3b. "Horizontal" method of double interpolation.

Lat.	*Declination*

45	31.2		32.0
45.7	*31.6*	***32.1***	*32.4*
46	31.8		32.6

TABLE P3c. "Vertical" method of double interpolation.

2. *"Vertical" method.* Use single interpolation for latitude for each tabulated value of declination, followed by single interpolation for declination. Consider the same example as above. First, find the amplitude for declination 21°5, latitude 45°7: $31°2+(0°7\times 0°6)=31°6$. Next, repeat the process for declination 22°0: $32°0+(0°7\times 0°6)=32°4$. Finally, interpolate between 31°6 and 32°4 for declination 21°8: $31°6+\left(\frac{3}{5}\times 0°8\right)=32°1$. This is the equivalent of first inserting a new line for latitude 45°7, followed by single interpolation in this line, as shown in table P3c.

3. *Combined method.* Select a tabulated "base" value, preferably that nearest the given tabulated entering arguments. Next, find the correction to be applied, with its sign, for single interpolation of this base value both horizontally and vertically. Finally, add these two corrections algebraically and apply the result, in accordance with its sign, to the base value. In the example given above, the base value is 32°6, for declination 22°0 (21°8 is nearer 22°0 than 21°5) and latitude 46° (45°7 is nearer 46° than 45°). The correction for declination is $\frac{2}{5}\times(-)\,0°8=(-)\,0°3$. The correction for latitude is $0°3\times(-)\,0°6=(-)\,0°2$. The algebraic sum is $(-)\,0°3+(-)\,0°2=(-)\,0°5$. The interpolated value is then $32°6-0°5=32°1$. This is the method customarily used by navigators.

P4. Triple interpolation.—With three entering arguments, the process is similar to that for double interpolation. It would be possible to perform double interpolation for the tabulated value on each side of the given value of one argument, and then interpolate for that argument, but the method would be tedious. The only method commonly used by navigators is that of selecting a base value and applying corrections. Suppose, for instance, that the azimuth angle is desired for latitude 41°3, declination 21°9 contrary name, meridian angle 16°6 using H.O. Pub. No. 214. The base value (lat. 41°, dec. 22°, t 17°) is 162°6. The corrections are

lat. 41°3:	0.3 × (+) 0°1=	0°0
dec. 21°9:	0.2 × (−) 0°1=	0°0
t 16°6:	0.4 × (−) 1°0=(−)	0°4
	Total (−)	0°4.

The triple interpolated value is 162°6−0°4=162°2. A convenient navigational form for solving this problem is shown in article 2007 and appendix Q.

P5. Interpolation tables.—A number of frequently used navigation tables are provided with auxiliary tables to assist in interpolation. Table 32 (Logarithms of Numbers) provides columns of "d" (difference between consecutive entries) and auxiliary "proportional parts" tables. The auxiliary table for the applicable difference "d" is selected and entered with the digit of the additional place in the entering argument. The value taken from the auxiliary table is *added* to the base value for the next *smaller* number from the main table. Suppose the logarithm (mantissa) for 32747 is desired. The base value for 3274 is 51508, and "d" is 13. The auxiliary table for 13 is entered with 7, and the correction is found to be 9. If this is added to 51508, the interpolated value is found to be 51517. This is the same result that would be obtained by subtracting 51508 from 51521 (the logarithm for 3275) to obtain 13, multiplying this by 0.7, and adding the result (9) to 51508.

Tables 31 and 33 provide the difference between consecutive entries, but no proportional parts tables.

In H.O. Pub. No. 214, Δd and Δt values are given, with "multiplication tables" to make the correction. The use of these tables is explained in chapter XX. The Δd of H.O. Pub. No. 249 (vols. II, III) is similar, except that a sign is given and interpolation is always made from the tabulated value of declination next *smaller* than the given value. This table is explained in chapter XXI.

The *Nautical Almanac* "Increments and Corrections" are interpolation tables for the hourly entries of GHA and declination. The use of these tables and the interpolation tables of the *Air Almanac* is explained in chapter XVIII.

The method of table 3 of using additional decimal places is still another form of interpolation.

P6. Extrapolation.—The extending of a table is usually performed by assuming that the difference between the last few tabulated entries will continue at the same rate. This assumption is strictly correct only if the change is truly linear, but in most tables the assumption provides satisfactory results for a *slight* extension beyond tabulated values. The extent to which the assumption can be used reliably can often be determined by noting the last few differences. If the "second differences" (differences between consecutive differences) are nearly zero, the curve is nearly a straight line, for a short distance. But if consecutive second differences are appreciable, extrapolation is not reliable. For examples of linear and nonlinear relationships, refer to the first page of table 33 and compare the tabulated differences of the logarithms of secant (approximately linear on this page) and sine (nonlinear on this page).

As an example of extrapolation, consider table 27. Suppose the amplitude for latitude 45°, declination 24°3 is desired. The last declination entry is 24°0. The amplitude for declination 23°5 is 34°3, and for declination 24°0 it is 35°1. The difference is (+) 0°8. Assuming this same difference between declinations 24°0 and 24°5, one finds the value for 24°3 is $35^\circ1+\left(\frac{3}{5}\times 0^\circ8\right)=35^\circ6$. Below latitude 50° this table is so nearly linear that extrapolation can be carried to declination 30° without serious error.

For double or triple extrapolation, differences are found as in single interpolation.

P7. General comments.—As a general rule, the final answer should not be given to greater precision than tabulated values. A notable exception to this rule is the case where tabulated values are known to be exact, as in table P2a. A slight increase in accuracy can sometimes be attained by retaining one additional place in the solution until the final answer. Suppose, for instance, that the corrections for triple interpolation are (+)0.2, (+)0.3, and (−)0.3. The total correction is (+)0.2. If the total

correction, rounded to tenths, had been obtained from the sum of (+)0.17, (+)0.26, and (−)0.34, the correct total would have been (+)0.09=(+)0.1. The retaining of one additional place may be critical if the correction factors end in 0.5. Thus, in double interpolation, one correction value might be (+)0.15, and the other (−)0.25. The correct total is (−)0.1. But if the individual differences are rounded to (+)0.2 and (−)0.2, the total is 0.0.

The difference used for establishing the proportion is also a matter subject to some judgment. Thus, if the latitude is 17°14.′6, it might be rounded to 17.°2 for many purposes. Slightly more accurate results can sometimes be obtained by retaining the minutes, using $\frac{14.6}{60}$ instead of 0.2. If the difference to be multiplied by this proportion is small, the increase in accuracy gained by using the more exact value is small, but if the difference is large, the gain might be considerable. Thus, if the difference is 0.°2, the correction by using either $\frac{14.6}{60}$ or 0.2 is less than 0.°05, or 0.°0 to the nearest 0.°1. But if the difference is 3.°2, the value by $\frac{14.6}{60}$ is 0.°8, and the value by 0.2 is 0.°6.

If the tabulated entries involved in an interpolation are all positive or all negative, the interpolation can be carried out on either a numerical or an algebraic basis. Most navigators prefer the former, carrying out the interpolation as if all entries were positive, and giving to the interpolated value the common sign of all entries. When both positive and negative entries are involved, all differences and corrections should be on an algebraic basis, and careful attention should be given to signs. Thus, if single interpolation is to be performed between values of (+)0.9 and (−)0.4, the difference is 0.9−(−0.4)=0.9+0.4=1.3. If the correction is 0.2 of this difference, it is (−)0.3 if applied to (+)0.9, and (+)0.3 if applied to (−)0.4. In the first case, the interpolated value is (+)0.9−0.3=(+)0.6. In the second case, it is (−)0.4+0.3=(−)0.1. If the correction had been 0.4 of the difference, it would have been (−)0.5 in the first case, and (+)0.5 in the second. The interpolated value would have been (+)0.9−0.5=(+)0.4, or (−)0.4+0.5=(+)0.1, respectively.

With practice, much of the interpolation used in navigation can be performed mentally, and is not customarily shown in the work forms. Notable exceptions are the interpolation for GHA and declination in the almanacs, and interpolation for declination (and meridian angle and latitude, if used) in H.O. Pub. No. 214.

Because of the variety in methods of interpolation used, solutions by different persons may differ slightly.

APPENDIX Q

WORK FORMS

The use of standard work forms reduces the probability of mistakes, by relieving the mind of details taken care of in the forms. It also provides a permanent record that can be checked, and that improves the appearance of the navigator's work book. The best forms to use are those which seem easiest, and provide a solution with the least probability of mistakes. The forms used throughout this book have been found effective in teaching navigation. The more commonly used ones are repeated on the following pages.

The individual navigator may wish to develop his own forms to reflect his own personal preferences. If the addition of a line or label, or the shifting of position of some part of a form assists in the avoidance of mistakes, or makes the solution seem easier, it serves a useful purpose. The mere changing for the sake of change, on the other hand, may encourage mistakes. The forms of this book are the result of considerable thought and the application of logic. The new navigator would do well to start with them, making changes only as the need arises.

The principal change sometimes made is the placing of a sight reduction form in a single column so that several observations can be solved in parallel columns. Methods such as H.O. Pub. No. 214 (Δd only) and H.O. Pub. No. 249 lend themselves readily to this type solution. A solution by cosine-haversine formula and some of the "short" methods of chapter XXI do not.

In these forms, and throughout the book, the standard abbreviations and symbols of appendix A are used.

The best use of a form is to first copy the entire form, then fill in *all* given or known information, and then proceed with the solution.

In the forms, entries such as "NS" or "TA" are given to indicate that a label is needed. Only the applicable label should be used. Where "Local date" or "Gr. date" appears, the actual date should be used. Zeros are used to indicate the units to use and, in general, the number of places that should be used. The numbers given in parentheses are article numbers where an example is given of the solution of a problem by the use of the form or forms.

APPENDIX R

BEAUFORT SCALE

WITH CORRESPONDING SEA STATE CODES

Beaufort number	Wind speed: knots	Wind speed: mph	Wind speed: meters per second	Wind speed: km per hour	Seaman's term	World Meteorological Organization (1964)	Estimating wind speed: Effects observed at sea	Estimating wind speed: Effects observed on land	Hydrographic Office: Term and height of waves, in feet	Hydrographic Office: Code	World Meteorological Organization: Term and height of waves, in feet	World Meteorological Organization: Code
0	under 1	under 1	0.0–0.2	under 1	Calm	Calm	Sea like mirror.	Calm; smoke rises vertically.	Calm, 0	0	Calm, glassy, 0	0
1	1–3	1–3	0.3–1.5	1–5	Light air	Light air	Ripples with appearance of scales; no foam crests.	Smoke drift indicates wind direction; vanes do not move.	Smooth, less than 1	1		
2	4–6	4–7	1.6–3.3	6–11	Light breeze	Light breeze	Small wavelets; crests of glassy appearance, not breaking.	Wind felt on face; leaves rustle; vanes begin to move.	Slight, 1–3	2	Calm, rippled, 0–⅓	1
3	7–10	8–12	3.4–5.4	12–19	Gentle breeze	Gentle breeze	Large wavelets; crests begin to break; scattered whitecaps.	Leaves, small twigs in constant motion; light flags extended.	Moderate, 3–5	3	Smooth, wavelets, ⅓–1⅔	2
4	11–16	13–18	5.5–7.9	20–28	Moderate breeze	Moderate breeze	Small waves, becoming longer; numerous whitecaps.	Dust, leaves, and loose paper raised up; small branches move.			Slight, 2–4	3
5	17–21	19–24	8.0–10.7	29–38	Fresh breeze	Fresh breeze	Moderate waves, taking longer form; many whitecaps; some spray.	Small trees in leaf begin to sway.	Rough, 5–8	4	Moderate, 4–8	4
6	22–27	25–31	10.8–13.8	39–49	Strong breeze	Strong breeze	Larger waves forming; whitecaps everywhere; more spray.	Larger branches of trees in motion; whistling heard in wires.			Rough, 8–13	5
7	28–33	32–38	13.9–17.1	50–61	Moderate gale	Near gale	Sea heaps up; white foam from breaking waves begins to be blown in streaks.	Whole trees in motion; resistance felt in walking against wind.				
8	34–40	39–46	17.2–20.7	62–74	Fresh gale	Gale	Moderately high waves of greater length; edges of crests begin to break into spindrift; foam is blown in well-marked streaks.	Twigs and small branches broken off trees; progress generally impeded.	Very rough, 8–12	5	Very rough, 13–20	6
9	41–47	47–54	20.8–24.4	75–88	Strong gale	Strong gale	High waves; sea begins to roll; dense streaks of foam; spray may reduce visibility.	Slight structural damage occurs; slate blown from roofs.	High, 12–20	6		
10	48–55	55–63	24.5–28.4	89–102	Whole gale	Storm	Very high waves with overhanging crests; sea takes white appearance as foam is blown in very dense streaks; rolling is heavy and visibility reduced.	Seldom experienced on land; trees broken or uprooted; considerable structural damage occurs.	Very high, 20–40	7	High, 20–30	7
11	56–63	64–72	28.5–32.6	103–117	Storm	Violent storm	Exceptionally high waves; sea covered with white foam patches; visibility still more reduced.		Mountainous, 40 and higher	8	Very high, 30–45	8
12	64–71	73–82	32.7–36.9	118–133	Hurricane	Hurricane	Air filled with foam; sea completely white with driving spray; visibility greatly reduced.	Very rarely experienced on land; usually accompanied by widespread damage.	Confused	9	Phenomenal, over 45	9
13	72–80	83–92	37.0–41.4	134–149								
14	81–89	93–103	41.5–46.1	150–166								
15	90–99	104–114	46.2–50.9	167–183								
16	100–108	115–125	51.0–56.0	184–201								
17	109–118	126–136	56.1–61.2	202–220								

Note: Since January 1, 1955, weather map symbols have been based upon wind speed in knots, at five-knot intervals, rather than upon Beaufort number.

APPENDIX S

MARITIME POSITIONS

With the 1958 edition, this appendix has been completely revised to reflect changes in United States Government approved names and to provide ready reference to sources of additional information about the individual entries. With very few exceptions, the newly approved names are native names. This revision presented an opportunity to provide a world-wide listing of such names. Well-known secondary names from older charts and publications are listed in parentheses, following the approved name. Abbreviations have been avoided wherever possible, except for the frequently used Island (I. or I), Islands (Is. or Is), and Light (Lt), which are usually abbreviated, except when used as headings.

The appendix contains 25 major headings (**ARCTIC REGIONS**). Lesser headings, given in boldface type (**Greenland**), have been chosen from both political and geographical subdivisions. Where desirable, a further subdivision is provided by the use of headings given in capitals and small capitals (STREYMOY (STROMO ISLAND)). Entries preceded by dashes follow each such capitalized heading, the dashes indicating that such entries are integral parts of that heading.

All entries appearing in italics (*Thule*) are listed in H.O. Pub. No. 150, *World Port Index*. All entries followed by the abbreviation Lt (Kajartalik: Lt) are listed in the appropriate H.O. light list for that area. Coordinates for these two types of entries were obtained from the above-mentioned publications. The remaining entries and their coordinates were selected from charts and sailing directions.

Where the larger political subdivision (State or nation) of a port (italic entry) is not otherwise apparent, this information is included as part of the entry. Because of changing political boundaries, geographic names or their spellings do not necessarily reflect recognition by the United States Government of the political status of an entry.

Because some of the newly approved names may not be familiar to all users, both the approved names and the secondary names are listed in the alphabetical index. For this reason, the alphabetical index should be used only as an aid to locating entries in the main listing. *In all cases* the main listing should be referred to for positive identification of the desired position and the approved name.

The index has been extensively cross-indexed, particularly in the case of transliterated and hyphenated names. In some instances strict alphabetization has been sacrificed in the interest of logic. For example, Spain, east coast and Spain, north coast are followed by Spain, south coast, rather than by Spain, Port-of-.

Each entry in the alphabetical index is identified by a four- or five-digit number corresponding to the numerical sequence in the main listing. Where two or more alphabetical entries possess identical or similar names, the general location is provided in parentheses, following the entry. Thus the user may easily distinguish between Aberdeen (Scotland) and Aberdeen (Washington).

Entries are listed in the following geographical arrangement.

Obtain from the predictions the high water and low water, one of which is before and the other after the time for which the height is required. The difference between the times of occurrence of these tides is the duration of rise or fall, and the difference between their heights is the range of tide for the above table. Find the difference between the nearest high or low water and the time for which the height is required.

Enter the table with the duration of rise or fall, printed in heavy-faced type, which most nearly agrees with the actual value, and on that horizontal line find the time from the nearest high or low water which agrees most nearly with the corresponding actual difference. The correction sought is in the column directly below, on the line with the range of tide.

When the nearest tide is high water, subtract the correction.

When the nearest tide is low water, add the correction.

APPENDIX U

EXTRACTS FROM TIDAL CURRENT TABLES

THE NARROWS, NEW YORK HARBOR, N. Y., 1958

f — flood, direction 340° true. e — ebb, direction 160° true.

[1] The values for the Hudson River are for the summer months, when the fresh-water discharge is a minimum.

[2] In Roundout Creek entrance between lights, eddies on the flood make navigation difficult. Little difficulty will be experienced on the ebb.

[3] Current does not flood.

[4] Current is rotary, turning clockwise. It flows NW. at time of "Slack, flood begins" at The Narrows; NE. 1 hour after maximum flood; SE. 1½ hours after "Slack, ebb begins"; and SW. 2 hours after maximum ebb.

[5] Flood begins, $-1^h\,45^m$; maximum flood, $-1^h\,50^m$; ebb begins, $-0^h\,15^m$; maximum ebb, $-0^h\,50^m$.

[6] In Sandy Hook Bay (except in southern extremity) the current is weak.

TABLE 3.—VELOCITY OF CURRENT AT ANY TIME

Use Table A for all places except those listed below for Table B.
Use Table B for Cape Cod Canal, Hell Gate, Chesapeake and Delaware Canal and all stations in Table 2 which are referred to them.

1. From predictions find the time of slack water and the time and velocity of maximum current (flood or ebb), one of which is immediately before and the other after the time for which the velocity is desired.
2. Find the interval of time between the above slack and maximum current, and enter the top of Table A or B with the interval which most nearly agrees with this value.
3. Find the interval of time between the above slack and the time desired, and enter the side of Table A or B with the interval which most nearly agrees with this value.
4. Find, in the table, the factor corresponding to the above two intervals and multiply the maximum velocity by this factor. The result will be the approximate velocity at the time desired.

Additional corrections for temperature and pressure are given on the following page.
For bubble sextant observations ignore dip and use the star corrections for Sun, planets, and stars.

The graph is entered with arguments temperature and pressure to find a zone letter; using as arguments this zone letter and apparent altitude (sextant altitude corrected for dip), a correction is taken from the table. This correction is to be applied to the sextant altitude in addition to the corrections for standard conditions (for the Sun, planets and stars from the inside front cover and for the Moon from the inside back cover).

ECLIPSES

There will be three eclipses, two of the Sun and one of the Moon.

I. *An Annular Eclipse of the Sun,* April 19. See map on page 6. The maximum duration of the annular phase is $7^{m}\ 07^{s}$.

II. *A Partial Eclipse of the Moon,* May 3. The eclipse begins at $12^{h}\ 00^{m}$ and ends at $12^{h}\ 26^{m}$; at the time of maximum eclipse 0·02 of the Moon's diameter is obscured. It is visible from the western part of North America, the Pacific Ocean, eastern Asia, the south-eastern part of the Indian Ocean, Australia, and Antarctica.

III. *A Total Eclipse of the Sun,* October 12. See map on page 7. The maximum duration of the total phase is $5^{m}\ 11^{s}$.

1958 MAY 31, JUNE 1, 2 (SAT., SUN., MON.)

$$\text{Latitude} = \text{corrected sextant altitude} - 1^\circ + a_0 + a_1 + a_2$$

The table is entered with L.H.A. Aries to determine the column to be used; each column refers to a range of 10°. a_0 is taken, with mental interpolation, from the upper table with the units of L.H.A. Aries in degrees as argument; a_1, a_2 are taken, without interpolation, from the second and third tables with arguments latitude and month respectively. a_0, a_1, a_2 are always positive. The final table gives the azimuth of *Polaris*.

The above table is for converting expressions in arc to their equivalent in time; its main use in this Almanac is for the conversion of longitude for application to L.M.T. (*added* if *west*, *subtracted* if *east*) to give G.M.T. or vice versa, particularly in the case of sunrise, sunset, etc.

Table I is for interpolating the L.M.T. of sunrise, twilight, moonrise, etc. for latitude. It is to be noted that the interpolation is not linear, so that when using this table it is essential to take out the required phenomenon for the latitude *less* than the true latitude. The table is entered with the nearest value of the difference between the times for the tabular latitude and the next higher one, and, in the appropriate column, with the difference between true latitude and tabular latitude; the correction so obtained is applied to the time for the tabular latitude; the sign of the correction can be seen by inspection.

TABLE II—FOR LONGITUDE

Long. East or West	Difference between the times for given date and preceding date (for east longitude) or for given date and following date (for west longitude)																	
	10m	20m	30m	40m	50m	60m	1h + 10m	1h + 20m	1h + 30m	1h + 40m	1h + 50m	1h + 60m	2h 10m	2h 20m	2h 30m	2h 40m	2h 50m	3h 00m
°	m	m	m	m	m	m	m	m	m	m	m	m	h m	h m	h m	h m	h m	h m
0	0	0	0	0	0	0	0	0	0	0	0	0	0 00	0 00	0 00	0 00	0 00	0 00

180	5	10	15	20	25	30	35	40	45	50	55	60	1 05	1 10	1 15	1 20	1 25	1 30

Table II is for interpolating the L.M.T. of moonrise, moonset and the Moon's meridian passage for longitude. It is entered with longitude and with the difference between the times for the given date and for the preceding date (in east longitudes) or following date (in west longitudes). The correction is normally *added* for west longitudes and *subtracted* for east longitudes, but if, as occasionally happens, the times become earlier each day instead of later, the signs of the corrections must be reversed.

MOON CORRECTION TABLE

The correction is in two parts; the first correction is taken from the upper part of the table with argument apparent altitude, and the second from the lower part, with argument H.P., in the same column as that from which the first correction was taken. Separate corrections are given in the lower part for lower (L) and upper (U) limbs. All corrections are to be **added** to apparent altitude, *but 30′ is to be subtracted from the altitude of the upper limb.*

For corrections for pressure and temperature see page A4.

For bubble sextant observations ignore dip, take the mean of upper and lower limb corrections and subtract 15′ from the altitude.

App. Alt. = Apparent altitude = Sextant altitude corrected for index error and dip.

* Stars used in H.O. 249 (A.P. 3270).
† Stars so indicated may be used with declination tables.
The numbers *following* the names are those used in A.P. 1618 (H.O. 218).

CORRECTIONS TO BE APPLIED TO MARINE SEXTANT ALTITUDES

MARINE SEXTANT ERROR

Sextant No.

Index Error

CORRECTIONS

In addition to sextant error and dip, corrections are to be applied for :

- Refraction
- Semi-diameter (for Sun and Moon)
- Parallax (for the Moon)
- Dome refraction if applicable.

CORRECTION FOR DIP OF THE HORIZON

To be subtracted from sextant altitude.

For angles greater than 180°, subtract 180° and add 12^h to the result.

The above table is for converting expressions in arc to their equivalent in time; its main use in this Almanac is for the conversion of longitude for application to L.M.T. (*added* if *west*, *subtracted* if *east*) to give G.M.T. or vice versa, particularly in the case of sunrise, sunset, etc.

INTERPOLATION OF MOONRISE, MOONSET FOR LONGITUDE

Add if longitude *west*.
Subtract if longitude *east*.

180	65	70	75	80	85	90

* When the Diff. is negative *subtract* correction if longitude *west* and *add* correction if longitude *east*.

CORRECTIONS TO BE APPLIED TO SEXTANT ALTITUDE

REFRACTION

To be subtracted from sextant altitude (referred to as observed altitude in A.P. 3270).

Height above sea level in units of 1,000 ft. — Sextant Altitude

1·2												
	−37	−45	−56	−67	−81	−95						

For these heights no temperature correction is necessary: take $f=1{\cdot}0$ and use $R=R_0$

When R_0 is less than 10′ or the height is greater than 35,000 ft. take $f=1{\cdot}0$ and use $R=R_0$

Choose the column appropriate to height, in units of 1,000 ft., and find the range of altitude in which the sextant altitude lies; the corresponding value of R_0 is the refraction, to be subtracted from sextant altitude, unless conditions are extreme. In that case find f from the lower table, with critical argument temperature. Use the table on the right to form the refraction, $R=R_0\times f$.

CORIOLIS (*Z*) CORRECTION

To be applied by moving the position line a distance *Z* to starboard (right) of the track in northern latitudes and to port (left) in southern latitudes. The argument is given as T.A.S. (True Air Speed) in A.P. 3270.

APPENDIX X

LONG-TERM ALMANAC

This appendix is intended for use when a more complete almanac is not available. It is based principally upon the fact that approximately correct values for the Greenwich hour angle and declination of the sun, and the Greenwich hour angle of Aries, can be obtained from an almanac that is exactly four years out of date. The differences in these values at intervals of exactly four years can be largely removed by applying an average correction to the values obtained from the tables of this appendix. The maximum error in an altitude computed by means of this appendix should not exceed 2′.0 for the sun or 1′.3 for stars.

This four-year, or quadrennial, correction varies throughout the year for the GHA of the sun (between about plus and minus one-fourth of a minute) and for the declination of the sun (between about plus and minus three-fourths of a minute). For the GHA of Aries the quadrennial correction is a constant, (+)1′.84. The appropriate quadrennial correction is applied once for each full four years which has passed since the base year of the tabulation (1956 in this appendix).

The tabulated values for GHA and declination of the sun and GHA of Aries are given in four columns, labeled 0, 1, 2, and 3. The "0" column contains the data for the leap year in each four-year cycle and the 1, 2, and 3 columns contain data for, respectively, the first, second, and third years following each leap year.

The GHA and declination of the sun are given at intervals of three days throughout the four-year cycle, except for the final days of each month, when the interval varies between one and four days. Linear interpolation is made between entries to obtain data for a given day. Additional corrections to the GHA of the sun of 15° per hour, 15′ per minute, and 15″ per second are made to obtain the GHA at a given time. Declination of the sun is obtained to sufficient accuracy by linear interpolation alone.

The GHA of Aries is given for each month of the four-year cycle. Additional corrections of 0°59′.14 per day, 15°02′.5 per hour, 15′ per minute, and 15″ per second are made to obtain the GHA at a given time.

The SHA and declination of 38 navigational stars are given for the base year, 1956.0. Annual (not quadrennial) corrections are made to these data to obtain the values for a given year and tenth of a year.

A multiplication table is included as an aid in applying corrections to tabulated values.

Sun tables. **1.** Subtract 1956 from the year and divide the difference by four, obtaining (*a*) a whole number, and (*b*) a remainder. Enter column indicated by remainder (*b*) and take out values on either side of given time and date.

2. Multiply quadrennial correction for each value by whole number (*a*) obtained in step 1 and apply to tabulated values.

3. Divide difference between corrected values by number of days (usually three) between them to determine daily change.

4. Multiply daily change by number of days and tenths since 0^h GMT of earlier tabulated date, and mark correction plus (+) or minus (−) as appropriate.

5. (GHA only.) Enter multiplication table with hours, minutes, and seconds of GMT, and take out corrections *A*, *B*, and *C*, respectively. These are all positive.

6. Apply corrections of steps 4 and 5 to corrected *earlier* values of step 2.

Example.—Find GHA and declination of sun at GMT $17^h13^m49^s$ on July 18, 1986.

Solution.—*Steps* 1 *and* 2: (1986−1956)÷4=7, remainder 2. Use column 2, and multiply quadrennial corrections by 7. Corrected values: GHA, July 16, 178°32′.0−(7×0′.23)=178°30′.4; July 19, 178°28′.0−(7×0′.20)=178°26′.6. Dec., July 16, 21°29′.2 N−(7×0′.35)=21°26′.8 N; July 19, 20°58′.9 N−(7×0′.39)=20°56′.2 N.

0^h July 16	21°26′.8 N	*Step 6*
d	20°59′.3 N	*Step 6*

Aries table. **1.** Subtract 1956 from the year and divide the difference by four, obtaining (*a*) a whole number, and (*b*) a remainder. Enter column indicated by remainder (*b*) and take out value for given month.

2. Enter multiplication table with whole number (*a*) of step 1, day of month, hours of GMT, minutes of GMT, and seconds of GMT, and take out corrections *D*, *E*, *F*, *G*, and *C*, respectively.

3. Add values of steps 1 and 2.

Example.—Find GHA ♈ at GMT $11^h06^m33^s$ on November 28, 1979.

Solution.—*Step* 1: (1979−1956)÷4=5, remainder 3. Use column 3.

	GHA ♈	
Nov.	38°33′.0	*Step 1*
D	9′.2	*Step 2*
E	27°35′.9	*Step 2*
F	165°27′.1	*Step 2*
G	1°30′.2	*Step 2*
C	8′.2	*Step 2*
GHA ♈	233°23′.6	*Step 3*

Stars table. **1.** Enter table with star name, and take out tabulated values.

2. Subtract 1956.0 from given year and tenth, and multiply annual correction by difference. Apply as correction (+or−, as appropriate) to value of step 1.

Example.—Find SHA and declination of Spica on September 11, 1995.

Solution.—From decimal table, September 11, 1995=1995.7. 1995.7−1956.0=39.7.

	SHA	
1956.0	159°16′.9	*Step 1*
39.7×(−)0′.79	(−)31′.4	*Step 2*
SHA	158°45′.5	*Step 2*

	Declination	
1956.0	10°55′.9 S	*Step 1*
39.7×0′.31	(+)12′.3	*Step 2*
d	11°08′.2 S	*Step 2*

To determine GHA of star, add GHA ♈ and SHA☆ for given time and date.

In **North latitude**, when the star is rising or East of the meridian, the tabulated azimuths are reckoned from North to East; and when the star is setting or West of the meridian, the tabulated azimuths are reckoned from North to West.

In **South latitude**, when the star is rising or East of the meridian, the tabulated azimuths are reckoned from South to East; and when the star is setting or West of the meridian, the tabulated azimuths are reckoned from South to West.

When the **latitude** and **declination** are of **different name**, the tables are to be entered with the supplement of the hour angle and the supplement of the tabulated azimuth is to be taken for the required true bearing.

AZIMUTH OR TRUE BEARING.

LATITUDE 52°. DECLINATION—SAME NAME AS—LATITUDE. **LATITUDE 52°.**

In **North latitude,** when the star is rising or East of the meridian, the tabulated azimuths are reckoned from North to East; and when the star is setting or West of the meridian, the tabulated azimuths are reckoned from North to West.

In **South latitude,** when the star is rising or East of the meridian, the tabulated azimuths are reckoned from South to East; and when the star is setting or West of the meridian, the tabulated azimuths are reckoned from South to West.

When the **latitude** and **declination** are of **different name,** the tables are to be entered with the supplement of the hour angle and the supplement of the tabulated azimuth is to be taken for the required true bearing.

Azimuth angle greater than 90°:
If DR latitude is greater than selected tabulated latitude, ΔL correction is *minus;* but for DR latitude less than selected tabulated latitude, the correction is *plus.*
Azimuth angle less than 90°:
If DR latitude is greater than selected tabulated latitude, ΔL correction is *plus;* but for DR latitude less than selected tabulated latitude, the correction is *minus.*

TABLES

TABLES

EXPLANATION OF TABLES

Table 1. Conversion Angle.—The angles listed in this table are the differences between the great-circle and rhumb line (Mercator) directions between various points. The table can be used either for converting rhumb line directions to equivalent great-circle directions, as in great-circle sailing; or the reverse, as in converting radio bearings to equivalent rhumb line bearings for plotting on a Mercator chart. The sign to be used for each process is indicated at the bottom of the table. As indicated, the sign given in the tabulation is reversed if the conversion angle is shown in italics.

The first one and one-half pages of the table, for differences of longitude of not more than 4°5, and middle latitudes between 0° and 85°, is intended primarily for use in converting radio bearings observed near a coast. In high latitudes it may be needed for converting visual bearings of objects a considerable distance away (art. 2522). This part of the table is entered with (1) the middle latitude between the craft and radio station or object, and (2) the difference of longitude between these two points. Do not use this part of the table if the latitudes are of contrary name (one north, the other south), if the difference of latitude is more than 10°, or if the difference of longitude is more than 4°5. Under any of these conditions, use the second part of the table.

For this part, select the page for the latitude nearest the latitude of departure in the case of great-circle sailing, or the latitude of the receiver in the case of radio bearings. On the selected page, the entering arguments are (1) difference of longitude (DLo) between the two points involved, and (2) the latitude of destination in the case of great-circle sailing, or the latitude of the transmitter in the case of radio bearings. For 0° latitude of departure or receiver, there is a single table. For all other latitudes, separate tables are provided for latitudes of same name and contrary name. For accurate results, use triple interpolation, as explained in article P4.

Use of the table is explained in articles 821 (great-circle sailing), 1204 (radio bearings), 1206 (consol), 2404 (azimuths by submarine periscope), and 2522 (visual bearings in high latitudes).

The conversion angles on the first one and one-half pages of the table were computed by means of the formula:

$$\tan \text{ conversion angle} = \sin Lm \tan \tfrac{1}{2} DLo,$$

in which Lm is the middle latitude, and DLo is the difference of longitude. This formula is based upon the assumption that the plot of a great-circle track on a Mercator chart is symmetrical, the axis of symmetry being the perpendicular bisector of the rhumb line connecting the two points. No error of practical significance in ordinary navigation is introduced by this erroneous assumption over the range covered by the first one and one-half pages of the table.

The remainder of the table was computed by means of the formula: conversion angle = initial great-circle direction $\sim$ rhumb line direction. The initial great-circle directions were computed by means of the formula:

$$\text{hav } C = \csc D \sec L_1 \, [\text{hav co } L_2 - \text{hav } (D \sim \text{co } L_1)],$$

in which C is the initial great-circle direction, D is the great-circle distance in arc units, L_1 is the latitude of departure (or receiver), and L_2 is the latitude of the destination (or transmitter). The distance D was computed by means of the formula:

$$\text{hav } D = \text{hav } DLo \cos L_1 \cos L_2 + \text{hav } (L_1 \sim L_2),$$

in which the notation is the same as above.

The rhumb line directions were computed by means of the formula:

$$\tan C = \frac{DLo}{m},$$

in which C is the rhumb line direction, and $m = M_1 \sim M_2$, the meridional parts of the two latitudes.

Table 2. Conversion of Compass Points to Degrees.—In this table the compass is boxed to 128 quarter points and the equivalent angle is given in degrees, minutes, and seconds. The naming of the quarter points, as given here, is one of several systems that have been used.

Table 3. Traverse Table.—This table provides the quantities needed for solution of plane right triangles, arranged in a form for convenient solution of the problems encountered in the various sailings (ch. VIII). Two sets of column headings are given to indicate the corresponding values in different problems. Thus, if DLo is used as entering argument in the first column, p is taken from the second column, but if D is used as entering argument in the first column, l is taken from the second column and p is taken from the third column. When the top line of column headings is used, the individual table is selected by means of the *latitude*. When the second line is used, the table is selected by means of the *course*.

The entering argument can be multiplied by any power of 10, including negative powers (art. O2), if the corresponding values taken from the table are multiplied by the same power. Thus, using the table for course 205°, if D=6 miles, l=5′.438, and p=2.536 miles; but if D=600 miles, l=543′.8, and p=253.6 miles; or if D=0.6 mile, l=0′.5438, and p=0.2536 mile.

In this table, DLo is difference of longitude, p is departure, D is distance, l is difference of latitude, and m is meridional difference (difference of meridional parts at two latitudes). In the solution of any right triangle, D can be considered the hypotenuse, and l and p the other two sides. The angle is that opposite side p. Also, if m is one of the short sides of a plane right triangle, DLo is the other side if the given angle is that opposite DLo. If the two short sides are known, the angle opposite one of them can be determined from the tabulation on the right if the table is entered with the quotient found by dividing this side by the other short side.

The use of this table in the solution of problems of the various sailings is given in chapter VIII.

The top decimal in each individual table is a natural trigonometric function, the p, l column being cosines, the p column being sines, the DLo, D column being secants, and the DLo column being tangents. The decimals below the top line are multiples of the top value. The decimals in the center column to the right of the double line are natural tangents at intervals of 0°.1. For additional decimal places, use table 31.

Table 4. Conversion Table for Meridional Parts.—The meridional parts given in table 5 are for the Clarke spheroid of 1866. The values given in table 4 can be applied as corrections to those of table 5 to obtain the meridional parts for the international spheroid, the Clarke spheroid of 1880, and the sphere. Data on these spheroids are given in appendix D.

An additional decimal place is given in this table to provide greater accuracy for interpolated values.

Table 5. Meridional Parts.—In this table the meridional parts used in the construction of Mercator charts and in Mercator sailing are tabulated to one decimal place for each minute of latitude from the equator to the poles. The use of the table is explained in articles 307 and 817.

The table was computed by means of the formula:

$$M = a \log_e 10 \log \tan\left(45° + \frac{L}{2}\right) - a\left(e^2 \sin L + \frac{e^4}{3} \sin^3 L + \frac{e^6}{5} \sin^5 L + \ldots\right),$$

in which

M is the number of meridional parts between the equator and the given latitude,

a is the equatorial radius of the earth, expressed in minutes of arc of the equator, or

$$a = \frac{21{,}600}{2\pi} = 3437.74677078 \ (\log = 3.5362738827),$$

$\log_e$ is the natural (Naperian) logarithm, using the base e=2.71828182846,
$\log_e 10=2.30258509299$ (log=0.3622156886),
L is the latitude,
e is the ellipticity of the earth, or $\sqrt{2f-f^2}=0.08227185422$ (log=8.9152512855−10),
and
f is the flattening of the earth, or $f=\frac{1}{294.98}=0.00339006034$ (log=7.5302074283−10).

Using these values,

$a \log_e 10=7915.704468$ (log=3.8984895715)

$ae^2=23.268932$ (log=1.3667764504)

$\frac{ae^4}{3}=0.052500$ (log=8.7201593034−10)

$\frac{ae^6}{5}=0.000213$ (log=6.3283796034−10).

Hence, the formula becomes

$$M=7915.704468 \log \tan\left(45°+\frac{L}{2}\right)-23.268932 \sin L-0.052500 \sin^3 L-0.000213 \sin^5 L \ldots$$

The constants used in this derivation and in the table are based upon the Clarke spheroid of 1866 (app. D), the standard reference spheroid used for charting North America.

Table 6. Length of a Degree of Latitude and Longitude.—This table gives the length of one degree of latitude and longitude at intervals of 1° from the equator to the poles. In the case of latitude, the values given are the lengths of the arcs extending half a degree on each side of the tabulated latitudes. Lengths are given in nautical miles, statute miles, feet, and meters.

The values were computed in meters, using the Clarke spheroid of 1866 (app. D), and converted to other units by the factors given in appendix D. The following formulas were used:

$$M=111{,}132.09-566.05 \cos 2L+1.20 \cos 4L-0.002 \cos 6L+ \ldots$$
$$P=111{,}415.13 \cos L-94.55 \cos 3L+0.12 \cos 5L- \ldots$$

in which M is the length of 1° of the meridian (latitude), L is the latitude, and P is the length of 1° of the parallel (longitude).

Table 7. Distance of an Object by Two Bearings.—To determine the distance of an object as a vessel passes it, observe two relative bearings (right or left) of the object, and note the time interval between bearings. Enter this table with the two bearings. Multiply the distance run between bearings by the number in the first column to find the distance of the object at the time of the second bearing, and by the number in the second column to find the distance when abeam. Use of the table is explained in article 910.

The table was computed by solving plane oblique and right triangles (art. O42).

Table 8. Distance of the Horizon.—This table gives the distance, in nautical and statute miles, of the visible horizon for various heights of eye from 1 to 200,000 feet. The actual distance varies somewhat as refraction changes. Also, the formulas used contain an approximation which introduces an error of a few tenths of a mile at the greatest heights tabulated. However, the error is generally less than that introduced by nonstandard atmospheric conditions. Since the earth's ellipticity is not considered, the table can be used at any place on the earth, without appreciable error.

Use of the table is explained in articles 916 (visibility of lights), 1208 (radar), 1606 (dip), and 1608 (wave height).

The table was computed by means of the formulas:

nautical miles: $D=1.144\sqrt{h}$,

statute miles: $D=1.317\sqrt{h}$,

in which D is the distance of the horizon in miles, and h is the height above the surface in feet. The constants 1.144 and 1.317 are based upon the mean radius of the earth according to the Clarke spheroid of 1866 (app. D).

Table 9. Distance by Vertical Angle.—This table provides means for determining the distance of an object of known height above sea level. The vertical angle between the top of the object and the visible (sea) horizon (the sextant altitude) is measured and corrected for index error and dip only. If the visible horizon is not available as a reference, the angle should be measured to the bottom of the object, and dip short of the horizon (tab. 22) used in place of the usual dip correction. This may require several approximations of distance by alternate entries of tables 9 and 22 until the same value is obtained twice. The table is entered with the difference in the height of the object and the height of eye of the observer, in feet, and the corrected vertical angle; and the distance in nautical miles is taken directly from the table. An error may be introduced if refraction differs from the standard value used in the computation of the table. Use of the table is explained in article 905. Other references to its use are given in articles 609, 4119, and 4127.

The table was computed by means of the formula:

$$D=\sqrt{\left(\frac{\tan \alpha}{0.000246}\right)^2+\frac{H-h}{0.74736}}-\frac{\tan \alpha}{0.000246},$$

in which D is the distance in nautical miles, α is the corrected vertical angle, H is the height of the top of the object in feet, and h is the height of eye of the observer, in feet. The constants 0.000246 and 0.74736 are based upon the mean refraction (0.0784).

Table 10. Direction and Speed of True Wind.—This table provides a means of converting apparent wind, observed aboard a moving craft, to true wind. To use the table, divide the apparent wind, in knots, by the vessel's speed, also in knots. This gives the apparent wind speed in units of ship's speed. Enter the table with this value and the difference between the heading and the apparent wind direction. The values taken from the table are (1) the difference between the heading and the true wind direction, and (2) the speed of the true wind in units of ship's speed. The true wind is on the same side as the apparent wind, and from a point farther aft. To convert wind speed in units of ship's speed to speed in knots, multiply by the vessel's speed in knots. The steadiness of the wind and the accuracy of its measurement are seldom sufficient to warrant interpolation in this table. If speed of the true wind and relative direction of the apparent wind are known, enter the column for direction of the apparent wind, and find the speed of the true wind, in units of ship's speed. The number to the left is the relative direction of the true wind. The number on the same line in the side columns is the speed of the apparent wind in units of ship's speed. Two solutions are possible if speed of the true wind is less than the ship's speed. Article 3709 explains the use of this table, and also a graphical solution of the problem.

The table was computed by solving the triangle involved in a graphical solution, using the formulas:

$$\tan \alpha=\frac{\sin B_A}{S_A-\cos B_A},$$

$$B_T=B_A+\alpha,$$

$$S_T=\frac{\sin B_A}{\sin \alpha},$$

in which α is an auxiliary angle, B_A is the difference between the heading and the apparent wind direction, S_A is the speed of the apparent wind in units of ship's speed, B_T is the difference between the heading and the true wind direction, and S_T is the speed of the true wind in units of ship's speed.

Table 11. Correction of Barometer Reading for Height Above Sea Level.—If simultaneous barometer readings at different heights are to be of maximum value in weather analysis, they should be converted to the corresponding readings at a standard height, usually sea level. To convert the observed barometer reading to this level, enter this table with the outside temperature and the height of the barometer above

sea level. The height of a barometer is the height of its sensitive element; in the case of a mercurial barometer, this is the height of the free surface of mercury in the cistern. The correction taken from this table applies to the readings of any type barometer, and is always *added* to the observed readings, unless the barometer is below sea level. Use of the table is explained in articles 3706 and 4119.

The correction was computed by means of the formula:

$$C=29.92126\left[1-\frac{1}{\text{antilog}\left(\frac{0.0081350H}{T+0.00178308H}\right)}\right],$$

in which

C is the correction in inches of mercury,

H is the height of the barometer above sea level in feet, and,

T is the mean temperature, in degrees Rankine (degrees Fahrenheit plus 459°.67), of the air between the barometer and sea level. At sea, the outside air temperature is sufficiently accurate for this purpose.

Table 12. Correction of Barometer Reading for Gravity.—The height of the mercury column of a mercurial barometer is affected by the force of gravity, which changes with latitude and is approximately equal along any parallel of latitude. The average gravitational force at latitude 45°32′40″ is used as the standard for calibration. This table provides a correction to convert the observed reading at any other latitude to the corresponding value at latitude 45°32′40″, so that it will have maximum value in weather analysis of an area. Enter the table with the latitude, take out the correction, and apply in accordance with the sign given. This correction does not apply to aneroid barometers. Use of the table is further explained in article 3706.

The correction was computed by means of the formula:

$$C=B\,(-0.002637\cos 2L+0.000006\cos^2 2L-0.000050),$$

in which

C is the correction in inches,

B is the observed reading of the barometer (corrected for temperature and instrumental errors) in inches of mercury. This table was computed for a standard height of 30 inches, and

L is the latitude.

Table 13. Correction of Barometer Reading for Temperature.—Because of the difference in expansion of the mercury column of a mercurial barometer and that of the brass scale by which the height is measured, a correction should be applied to the reading when the temperature differs from the standard used for calibration of the instrument. To find the correction, enter this table with the temperature in degrees Fahrenheit, and the barometer reading. Apply the correction in accordance with the sign given. This correction does not apply to aneroid barometers. Use of the table is further explained in article 3706.

The standard temperature used for calibration is 32° F for the mercury, and 62° F for the brass. The correction was computed by means of the formula:

$$C=-B\,\frac{m\,(T-32^\circ)-l\,(T-62^\circ)}{1+m\,(T-32^\circ)},$$

in which

C is the correction in inches,

B is the observed reading of the barometer in inches of mercury,

m is the coefficient of cubical expansion of mercury=0.0001010 cubic inches per degree F,

l is the coefficient of linear expansion of brass=0.0000102 inches per degree F, and

T is the temperature of the attached thermometer in degrees F.

Substituting the values for m and l and simplifying:

$$C=-B\,\frac{T-28^\circ.630}{1.1123T+10978^\circ}.$$

The minus sign before B indicates that the correction is negative if the temperature is more than 28°.630.

Table 14. Conversion Table for Millibars, Inches of Mercury, and Millimeters of Mercury.—The reading of a barometer in inches or millimeters of mercury corresponding to a given reading in millibars can be found directly from this table. Use of the various units is discussed in article 3702.

The formula for the pressure in millibars is:

$$P=\frac{B_mDg}{1000},$$

in which

P is the atmospheric pressure in millibars,

B_m is the height of the column of mercury in millimeters,

D is the density of mercury = 13.5951 grams per cubic centimeter, and

g is the standard value of gravity = 980.665 dynes. Substituting numerical values:

$$P=1.33322B_m,$$

and

$$B_m=\frac{P}{1.33322}=0.750064P.$$

Since one millimeter = 0.03937 inches,

$$B_i=\frac{0.03937P}{1.33322}=0.0295300P,$$

in which B_i is the height of the column of mercury, in inches.

Table 15. Conversion Table for Thermometer Scales.—Enter this table with temperature Fahrenheit, F; Celsius (centigrade), C; or Kelvin, K; and take out the corresponding readings on the other two temperature scales. Temperature measurement is discussed in article 3711.

On the Fahrenheit scale, the freezing temperature of pure water at standard sea-level pressure is 32°, and the boiling point under the same conditions is considered 212°. The corresponding temperatures are 0° and 100°, respectively, on the Celsius scale and 273°15 and 373°15, respectively, on the Kelvin scale. The value of (−) 273°15 C for absolute zero, the starting point of the Kelvin scale, is the value recognized officially by the National Bureau of Standards of the United States.

The formulas for converting the reading of one scale to the corresponding values of the others, derived from the figures given above, are:

$$C=\frac{5}{9}(F-32^\circ)=K-273^\circ 15,$$

$$F=\frac{9}{5}C+32^\circ=\frac{9}{5}K-459^\circ 67,$$

$$K=\frac{5}{9}(F+459^\circ 67)=C+273^\circ 15,$$

in which all temperatures are in degrees.

Table 16. Relative Humidity.—To determine the relative humidity of the atmosphere, enter this table with the dry-bulb (air) temperature (F), and the *difference* between the dry-bulb and wet-bulb temperatures (F). The value taken from the table is the approximate percentage of relative humidity. If the dry-bulb and wet-bulb temperatures are the same, relative humidity is 100 percent. Use of the table is explained in article 3713.

The table was computed by means of the formula:

$$R=\frac{100e}{e_w},$$

in which

R is the approximate relative humidity in percent,

e is the ambient vapor pressure, and

e_w is the saturation vapor pressure over water at dry-bulb temperature.

Professor Ferrel's psychrometric formula was used for computation of e:

$$e=e'-\left[0.000367P\ (t-t')\left(1+\frac{t'-32^\circ}{1571}\right)\right],$$

in which

e is the ambient vapor pressure in millibars,

e′ is the saturation vapor pressure in millibars at wet-bulb temperature with respect to water.

P is the atmospheric pressure (the millibar equivalent of 30 inches of mercury is used for this table),

t is the dry-bulb temperature in degrees Fahrenheit, and

t′ is the wet-bulb temperature in degrees Fahrenheit.

The values of e_w were taken from the International Meteorological Organization Publication Number 79, 1951, table 2, pages 82–83.

Table 17. Dew Point.—To determine the dew point, enter this table with the dry-bulb (air) temperature (F), and the *difference* between the dry-bulb and wet-bulb temperatures (F). The value taken from the table is the dew point in degrees Fahrenheit. If the dry-bulb and wet-bulb temperatures are the same, the air is at or below the dew point. Use of the table is explained in articles 3713 and 3715.

The values given in this table were obtained (1) by determining the saturation vapor pressure e′ for the given temperature T (in degrees Rankine) by means of the following formula:

$$\log_{10} e' = -7.90298\left(\frac{671.67}{T}-1\right)+5.02808\log_{10}\frac{671.67}{T}-1.3816\times10^{-7}\left(10^{11.344\left(1-\frac{T}{671.67}\right)}-1\right)$$
$$+8.1328\times10^{-3}\left(10^{-3.49149\left(\frac{671.67}{T}-1\right)}-1\right)+\log_{10}1013.246,$$

(2) by determining the ambient vapor pressure by means of Ferrel's formula (see explanation to table 16), (3) by substituting e for e′ in the formula of (1) to obtain the temperature T of the wet bulb when saturation occurs (to the precision of table 17), and (4) by converting the wet-bulb temperature (T) to the dry-bulb temperature T′ by means of the equation:

$$T'=T+(t-t'),$$

where $(t-t')$ is the depression of the wet-bulb temperature. Tables evaluating e′ in terms of T for use in steps (1) and (3) are given in International Meteorological Organization Publication Number 79, 1951, and the Smithsonian Meteorological Tables, Sixth Revised Edition, 1951.

Table 18. Speed Table for Measured Mile.—To find the speed of a vessel traversing a measured nautical mile in a given number of minutes and seconds of time, enter this table at the top or bottom with the number of minutes, and at either side with the number of seconds. The number taken from the table is speed in knots. Accurate results can be obtained by interpolating to the nearest 0.1 second. Use of the table is explained in articles 608 and 615.

This table was computed by means of the formula:

$$S=\frac{3600}{T},$$

in which S is speed in knots, and T is elapsed time in seconds.

Table 19. Speed, Time, and Distance.—To find the distance steamed at any given speed between 0.5 and 40 knots in any given number of minutes from 1 to 60, enter this table at the top with the speed, and at the left with the number of minutes. The number taken from the table is the distance in nautical miles. If hours are substituted for minutes, the tabulated distance should be multiplied by 60; if seconds are substituted for minutes, the tabulated distance should be divided by 60. Use of the table is explained in articles 608, 801, and P1.

The table was computed by means of the formula:

$$D=\frac{ST}{60},$$

in which D is distance in nautical miles, S is speed in knots, and T is elapsed time in minutes.

Table 20. Conversion Table for Nautical and Statute Miles.—This table gives the number of statute miles corresponding to any whole number of nautical miles from 1 to 100, and the number of nautical miles corresponding to any whole number of statute miles within the same range. The entering value can be multiplied by any

power of 10, including negative powers, if the corresponding value of the other unit is multiplied by the same power. Thus, 2,700 nautical miles are equivalent to 3,107.1 statute miles, and 0.3 statute mile is equivalent to 0.2607 nautical mile. Hence, to find the number of statute miles equal to 2463.2 nautical miles:

Nautical miles	*Statute miles*
2400. 0	2761. 9
63. 0	72. 5
0. 2	0. 2
2463. 2	2834. 6

Use of the table is explained in articles 205 and 607.

The table was computed by means of the conversion factors of appendix D:

1 nautical mile = 1.15077945 statute miles,
1 statute mile = 0.86897624 nautical mile.

Table 21. Conversion Table for Meters, Feet, and Fathoms.—The number of feet and fathoms corresponding to a given number of meters, and vice versa, can be taken directly from this table for any value of the entering argument from 1 to 120. The entering value can be multiplied by any power of 10, including negative powers, if the corresponding values of the other units are multiplied by the same power. Thus, 420 meters are equivalent to 1378.0 feet, and 11.2 fathoms are equivalent to 20.483 meters. Hence, to find the number of meters equal to 2163 feet:

Feet	*Meters*
2100	640
63	19
2163	659.

These units of measurement are discussed in article 607.

The table was computed by means of the relationships given in appendix D:

1 meter = 39.370079 inches,
1 foot = 12 inches,
1 fathom = 6 feet.

Approximately the same results would be obtained by using the direct conversion factors given in appendix D.

Table 22. Dip of the Sea Short of the Horizon.—If land, another vessel, or other obstruction is between the observer and the sea horizon, use the water line of the obstruction as the horizontal reference for altitude measurements, and substitute dip from this table for the dip of the horizon (height of eye correction) given in the *American Nautical Almanac* or other source. The values below the bold rules are for normal dip, the visible horizon being between the observer and the obstruction. Use of the table is explained in article 1606 and in the explanation of table 9.

The table was computed by means of the formula:

$$D_s = 0.4156d + 0.5658\frac{h}{d},$$

in which D_s is the dip short of the sea horizon, in minutes; d is the distance to the water line of the obstruction, in nautical miles; and h is the height of eye of the observer above sea level, in feet.

Table 23. Altitude Correction for Air Temperature.—This table provides a correction to be applied to the altitude of a celestial body when the air temperature varies from the 50° F used for determining mean refraction by means of the *Nautical Almanac*. For maximum accuracy, apply index correction and dip to sextant altitude first, obtaining rectified (apparent) altitude for use in entering this table. Enter the table

with altitude and air temperature in degrees Fahrenheit. Apply the correction, in accordance with its tabulated sign, to altitude. Use of the table is explained principally in chapter XVI, and especially in articles 1614 and 1632.

The table was computed by means of the formula:

$$\text{Correction} = R_m\left(1-\frac{510}{460+T}\right),$$

in which R_m is mean refraction and T is temperature in degrees Fahrenheit.

Table 24. Altitude Correction for Atmospheric Pressure.—This table provides a correction to be applied to the altitude of a celestial body when the atmospheric pressure varies from the 29.83 inches (1010 millibars) used for determining mean refraction by means of the *Nautical Almanac*. For most accurate results, apply index correction and dip to sextant altitude first, obtaining rectified (apparent) altitude for use in entering this table. Enter the table with altitude and atmospheric pressure. Apply the correction to altitude, *adding* if the pressure is less than 29.83 inches and *subtracting* if it is more than 29.83 inches. Use of the table is explained principally in chapter XVI, and especially in articles 1615 and 1632.

The table was computed by means of the formula:

$$\text{Correction} = R_m\left(1-\frac{P}{29.83}\right),$$

in which R_m is mean refraction and P is atmospheric pressure in inches of mercury.

Table 25. Meridian Angle and Altitude of a Body on the Prime Vertical Circle.—A celestial body having a declination of contrary name to the latitude does not cross the prime vertical above the celestial horizon, its nearest approach being at rising or setting.

If the declination and latitude are of the same name, and the declination is numerically greater, the body does not cross the prime vertical, but makes its nearest approach (in azimuth) when its meridian angle, east or west, and altitude are as shown in this table, these values being given in italics above the heavy line. At this time the body is stationary in azimuth.

If the declination and latitude are of the same name and numerically equal, the body passes through the zenith as it crosses both the celestial meridian and the prime vertical, as shown in the table.

If the declination and latitude are of the same name, and the declination is numerically less, the body crosses the prime vertical when its meridian angle, east or west, and altitude are as tabulated in vertical type below the heavy line.

The table is entered with declination of the celestial body and the latitude of the observer. Computed altitudes are given, no allowance having been made for refraction, dip, parallax, etc. The tabulated values apply to any celestial body, but values are not given for declination greater than 23° because the tabulated information is generally desired for the sun only. Use of the information given in this table is discussed in articles 2107, 2125, and 2306.

The table was computed by means of the following formulas, derived by Napier's rules (art. O42):

Nearest approach (in azimuth) to the prime vertical:

$$\csc h = \sin d \csc L,$$
$$\sec t = \tan d \cot L.$$

On the prime vertical:

$$\sin h = \sin d \csc L,$$
$$\cos t = \tan d \cot L.$$

In these formulas, h is the altitude, d is the declination, L is the latitude, t is the meridian angle.

Table 26. Latitude and Longitude Factors.—The latitude obtained by solution of an ex-meridian sight (art. 2103) is inaccurate if the longitude used in determining the meridian angle is incorrect. Similarly, the longitude obtained by solution of a time sight (art. 2106) is inaccurate if the latitude used in the solution is incorrect, unless the celestial body is on the prime vertical. This table gives the errors resulting from unit errors in the assumed values used in the computations. There are two columns for each tabulated value of latitude. The first gives the latitude factor, f, which is the error in minutes of latitude for a one-minute error of longitude. The second gives the longitude factor, F, which is the error in minutes of longitude for a one-minute error of latitude. In each case, the total error is the factor multiplied by the number of minutes error in the assumed value. Although the factors were originally intended for use in correcting ex-meridian altitudes and time-sight longitudes, they have other uses which may suggest themselves.

The azimuth angle used for entering the table can be measured from *either* the north or south, through 90°; or it may be measured from the elevated pole, through 180°. If the celestial body is in the southeast (090°–180°) or northwest (270°–360°) quadrant, the f correction is applied to the northward if the correct longitude is east of that used in the solution, and to the southward if the correct longitude is west of that used; while the F correction is applied to the eastward if the correct latitude is north of that used in the solution, and to the westward if the correct latitude is south of that used. If the body is in the northeast (000°–090°) or southwest (180°–270°) quadrant, the correction is applied in the opposite direction. These rules apply in both north and south latitude.

The table was computed by means of the formulas:

$$f=\cos L \tan Z=\frac{1}{\sec L \cot Z}=\frac{1}{F},$$

$$F=\sec L \cot Z=\frac{1}{\cos L \tan Z}=\frac{1}{f},$$

in which f is the tabulated latitude factor, L is the latitude, Z is the azimuth angle, and F is the tabulated longitude factor.

Table 27. Amplitudes.—This table lists amplitudes of celestial bodies at rising and setting. Enter with the declination of the body and the latitude of the observer. The value taken from the table is the amplitude when the *center* of the body is on the *celestial* horizon. For the sun, this occurs when the lower limb is a little more than half a diameter above the visible horizon. For the moon it occurs when the upper limb is about on the horizon. Use the prefix E if the body is rising, and W if it is setting; use the suffix N or S to agree with the declination of the body. Table 28 can be used with reversed sign to correct the tabulations to the values for the visible horizon. Use of table 27 is explained in article 2125.

The table was computed by means of the following formula, derived by Napier's rules (art. O42):

$$\sin A=\sec L \sin d,$$

in which A is the amplitude, L is the latitude of the observer, and d is the declination of the celestial body.

Table 28. Correction of Amplitude as Observed on the Visible Horizon.—This table contains a correction to be applied to the amplitude observed when the center of a celestial body is on the visible horizon, to obtain the corresponding amplitude when the center of the body is on the celestial horizon. For the sun, a planet, or a star, apply the correction in the direction *away* from the elevated pole, thus *increasing* the *azimuth angle.* For the moon apply *half* the correction *toward* the elevated pole. This correction can be applied in the opposite direction to a value taken from table 27, to

find the corresponding amplitude when the center of a celestial body is on the visible horizon. The table was computed for a height of eye of 41 feet. For other heights normally encountered, the error is too small to be of practical significance in ordinary navigation. Use of the table is explained in article 2125.

The values in the table were determined by computing the azimuth angle when the center of the celestial body is on the visible horizon, converting this to amplitude, and determining the difference between this value and the corresponding value from table 27. Computation of azimuth angle was made for an altitude of (−)0°42.′0, determined as follows:

Dip at 41 feet height of eye	(−) 6.′2
Refraction at (−)6.′2 alt.	(−)35.′3
Irradiation of horizon	(−) 0.′6
Parallax (value for sun)	(+) 0.′1
	(−)42.′0.

Azimuth angle was computed by means of the formula:

$$\cos Z = \frac{\sin d + \sin h \sin L}{\cos h \cos L},$$

in which Z is the azimuth angle, d is the declination of the celestial body, h is the altitude (−0°42.′0), and L is the latitude of the observer.

Table 29. Altitude Factor.—In one minute of time from meridian transit the altitude of a celestial body changes by the amount shown in this table if the altitude is between 6° and 86°, the latitude is not more than 60°, and the declination is not more than 63°. The values taken from this table are used to enter table 30 for solving reduction to the meridian (ex-meridian) problems, explained in article 2103.

For upper transit, use the left-hand pages if the declination and latitude are of the same name (both north or both south) and the right-hand pages if of contrary name. For lower transit, use the values below the heavy lines on the last three contrary-name pages. When a factor is taken from this part of the table, the correction from table 30 is *subtracted* from the observed altitude to obtain the corresponding meridian altitude. All other corrections are added.

The table was computed by means of the formula:

$$a = 1.''9635 \cos L \cos d \csc (L \sim d),$$

in which a is the change of altitude in one minute from meridian transit (the tabulated value), L is the latitude of the observer, and d is the declination of the celestial body.

This formula can be used to compute values outside the limits of the table, but is not accurate if the altitude is greater than 86°.

Table 30. Change of Altitude in Given Time from Meridian Transit.—Enter this table with the altitude factor from table 29 and the meridian angle, in either arc or time units, and take out the difference between the altitude at the given time and the altitude at meridian transit. Enter the table separately with whole numbers and tenths of a, interpolating for t if necessary, and add the two values to obtain the total difference. This total can be applied as a correction to observed altitude to obtain the corresponding meridian altitude, adding for upper transit and subtracting for lower transit. This problem is further discussed in article 2103.

The table was computed by means of the formula:

$$C = \frac{at^2}{60},$$

in which C is the tabulated difference to be used as a correction to observed altitude, in minutes of arc; a is the altitude factor from table 29, in seconds of arc; and t is the meridian angle, in minutes of time.

This formula should not be used for determining values beyond the limits of the table, unless reduced accuracy is acceptable.

Table 31. Natural Trigonometric Functions.—This table gives the values of natural sines, cosecants, tangents, cotangents, secants, and cosines of angles from 0° to 180°, at intervals of 1′. For angles between 0° and 45° use the column labels at the top and the minutes at the left; for angles between 45° and 90° use the column labels at the bottom and the minutes at the right; for angles between 90° and 135° use the column labels at the bottom and the minutes at the left; and for angles between 135° and 180° use the column labels at the top and the minutes at the right. These combinations are indicated by the arrows accompanying the figures representing the number of degrees. For angles between 180° and 360°, subtract 180° and proceed as indicated above to obtain the numerical values of the various functions.

Differences between consecutive entries are shown in the "Diff. 1′" column to the right of each column of values of a trigonometric function, as an aid to interpolation. These differences are one-half line out of step with the numbers to which they apply, as in a critical table. Each difference applies to the values half a line above and half a line below. To determine the correction to apply to the value for the smaller entering angle, multiply the difference by the number of tenths of a minute $\left(\text{or } \frac{\text{seconds}}{60}\right)$ of the entering angle. Note whether the function is increasing or decreasing, and add or subtract the correction as appropriate, so that the interpolated value lies between the two values between which interpolation is made.

The logarithms of values given in this table are given in table 33. The trigonometric functions are explained in article O39.

Table 32. Logarithms of Numbers.—The first page of this table gives the complete common logarithm (characteristic and mantissa) of numbers 1 through 250. The succeeding pages give the mantissa only of the common logarithm of any number. Values are given for four significant digits of entering values, the first three being in the left-hand column, and the fourth at the heading of one of the other columns. Thus, the mantissa of a three-digit number is given in the column headed 0, on the line with the given number; while the mantissa of a four-digit number is given in the column headed by the fourth digit, on the line with the first three digits. As an example, the mantissa of 328 is 51587, while that of 3.284 is 51640. For additional digits, interpolation should be used. The difference between each tabulated mantissa and the next larger tabulated mantissa is given in the "d" column to the right of the smaller mantissa. This difference can be used to enter the appropriate proportional parts ("Prop. parts") auxiliary table to interpolate for the fifth digit of the given number. If an accuracy of more than five significant digits is to be preserved in a computation, a table of logarithms to additional decimal places should be used. For a number of one or two digits, use the first page of the table or add zeros to make three digits. That is, the mantissa of 3, 30, and 300 is the same, 47712. Interpolation on the first page of the table is not recommended. The second part should be used for values not listed on the first page.

Additional information on the nature and use of logarithms is given in article O10.

Table 33. Logarithms of Trigonometric Functions.—This table gives the common logarithms (+10) of sines, cosecants, tangents, cotangents, secants, and cosines of angles from 0° to 180°, at intervals of 1′. For angles between 0° and 45° use the column labels at the top and the minutes at the left; for angles between 45° and 90° use the column labels at the bottom and the minutes at the right; for angles between 90° and 135° use the column labels at the bottom and the minutes at the left; and for angles between 135° and 180° use the column labels at the top and the minutes at the right. These combinations are indicated by the arrows accompanying the figures representing the number of degrees. For angles between 180° and 360°, subtract 180° and proceed as indicated above to obtain the numerical values of the various functions.

Differences between consecutive entries are shown in the "Diff. 1′" columns as in table 31, except that one difference column is used for both sines and cosecants, another for both tangents and cotangents, and a third for both secants and cosines. These differences, given as an aid to interpolation, are one-half line out of step with the numbers to which they apply, as in a critical table. Each difference applies to the values half a line above and half a line below. To determine the correction to apply to the value for the smaller entering angle, multiply the difference by the number of tenths of a minute $\left(\text{or } \frac{\text{seconds}}{60}\right)$ of the entering angle. Note whether the function is increasing or decreasing, and add or subtract the correction as appropriate, so that the interpolated value lies between the two values between which interpolation is made.

Natural trigonometric functions are given in table 31. The trigonometric functions, both natural and logarithmic, are explained in article O39.

Table 34. Haversines.—This table lists the common logarithms (+10) of haversines, and natural haversines, of angles from 0° to 360°, at intervals of 1′. For angles between 0° and 180° use the degrees as given at the tops of the columns and the minutes at the left; for angles between 180° and 360° use the degrees as given at the bottoms of the columns and the minutes at the right.

A haversine is half of a versed sine:

$$\text{hav } A = \tfrac{1}{2} \text{ ver } A = \tfrac{1}{2}\,(1-\cos A) = \sin^2 \tfrac{1}{2} A.$$

It is further discussed in article O39. Examples of the use of haversines are given in articles 822 and 2109.

For the **sun**, a **planet**, or a **star**, apply the correction to the observed amplitude in the direction **away** from the elevated pole. For the **moon** apply **half** the correction **toward** the elevated pole.
